Toxic: According to the U.S. Institute of Medicine, conservative practice recommends that adults not consume more than 100 mg of pyridoxine daily, the tolerable upper intake level (UL) for adults.[5] However, no studies have produced evidence of sensory nerve damage, as confirmed by objective neurological examination, at intakes of pyridoxine below 200 mg/day. Intakes up to 200 mg/day are usually safe in adults. Regardless, a daily dose of 500 mg should never be exceeded, even under physician supervision. Most cases of toxicity, particularly sensory neuropathy, have developed in individuals who have ingested doses of pyridoxine in excess of 1000 mg/day for extended periods.[9]

Pregnant and lactating women should avoid daily doses of vitamin B_6 greater than 100 mg daily. Vitamin B_6 crosses the placenta. However, available evidence suggests safe use during pregnancy.

Pediatric (<18 Years)

Dietary:

Infants, birth to 6 months: 0.1 mg/(AI, adequate intake)
Infants, 7 to 12 months: 0.3 mg/day (AI)
Children, 1 to 3 years: 0.5 mg/day (RDA)
Children 4 to 8 years: 0.6 mg/day (RDA)
Children 9 to 13 years: 1.0 mg/day (RDA)
Adolescents, 14 to 18 years: 1.2 mg/day for females; 1.3 mg/day for males (RDA)

Supplemental/Maintenance

Vitamin B_6 is usually not recommended for children under 12 years of age.

Pharmacological/Therapeutic

Viatmin B_6 is usually not recommended for children under 12 years of age, except intravenous administration for pyridoxine-dependent seizures in infants.

Toxic: Tolerable upper intake level (UL) for vitamin B_6:

Infants, birth to 12 months: Not possible to establish.
Children, 1 to 3 years: 30 mg/day
Children, 4 to 8 years: 40 mg/day
Children, 9 to 13 years: 60 mg/day
Adolescents, 14 to 18 years: 80 mg/day

Laboratory Values

At present, there is no generally accepted test for assessing vitamin B_6 status.

Plasma pyridoxal 5'-phosphate (P5P, PLP; active form of B_6): Levels less than 30 nmol/L indicate deficiency.

Plasma total vitamin B_6: Levels less than 40 nmol/L indicate deficiency.

Urinary 4-pyridoxic acid: Levels less than 3.0 µmol/day indicate deficiency; 4-pyridoxic acid is the major urinary metabolite of B_6.

Erythrocyte glutamic-pyruvic (alanine) transaminase index (EGPT): A ratio greater than 1.25 (or 1.5) indicates deficiency, depending on the amount of PLP added and the method of testing.

Enzymatic assays run before and after addition of PLP can be used to generate an activity coefficient ratio for this PLP-dependent enzyme. This represents the functional availability of erythrocyte vitamin B_6 in its coenzyme form. The value increases with vitamin B_6 deficiency.

Erythrocyte glutamic-oxaloacetic (aspartate) transaminase index (EGOT): This dual enzymic assay is effective to detect and measure human deficiencies of both PLP and activity of this PLP-dependent enzyme.

Serum glutamic-oxaloacetic transaminase (SGOT) reactivation: Although primarily used to diagnose and monitor the course of liver disease, decreased levels in this standard measure of aspartate transaminase (AST) can indicate pyridoxine deficiency.

Serum B_6: Radioimmunoassay (RIA) of serum pyridoxal phosphate can be used to detect both vitamin B_6 deficiency and vitamin B_6 toxicity.

Reference range: 18 to 175 nmol/L.

Tryptophan load test (tryptophan challenge): Urinary xanthurenic acid excretion greater than 65 µmol/L indicates deficiency.

Tryptophan catabolism is PLP dependent. Thus, an oral tryptophan dose (50 mg/kg for children and up to 2 g/kg for

adults) is administered and xanthurenic acid measured to provide a functional assessment of vitamin B_6 status.

SAFETY PROFILE

Overview

Although water soluble and efficiently excreted, vitamin B_6 occupies the unenviable position of being the only B vitamin for which toxicity is a reasonable concern. Although typical dosage levels in most available supplements are unlikely to produce adverse effects in most healthy individuals, concern surrounds this nutrient, as codified by regulatory agencies worldwide.

Sensory neuropathy is the primary adverse effect caused by chronic pyridoxine overdose. Other effects reported, but without established frequency, include nausea, headache, seizures (after very large intravenous doses), insomnia, suppressed lactation, increased AST levels, decreased serum folic acid levels, and miscellaneous allergic reactions.

Nutrient Adverse Effects

Peripheral neuropathy characterized by loss of reflexes and paresthesias and pain in the extremities constitutes the primary toxic effect associated with vitamin B_6 administration. Such adverse effects are almost exclusively associated with high-dose intake, in excess of 1000 mg daily, for an extended period. However, several case reports describe individuals exhibiting sensory neuropathies at dosage levels of less than 500 mg daily over several months.

Parry and Bredesen[7] described sensory neuropathy in 16 patients associated with pyridoxine abuse, defining "low-dose pyridoxine" intake as "0.2 to 5g"/day. They noted that "duration of consumption before symptoms was inversely proportional to the daily intake." Furthermore, they observed that for "all patients with adequate follow-up, improvement followed discontinuation of pyridoxine."[7]

Subsequently, Dalton and Dalton[8] published a paper from a controlled trial describing a "newly recognised neurotoxic syndrome due to pyridoxine (B_6) overdose." They reported an elevated serum B_6 level in 172 women, "of whom 60% had neurological symptoms, which disappeared when B_6 was withdrawn and reappeared in 4 cases when B_6 was restarted." They observed that the "mean dose of B_6 in the 103 women with neurological symptoms was 117 ± 92 mgs, compared with 116.2 ± 66 mgs in the control group" and noted "a significant difference (P less than 0.01) in the average duration of ingestion of B_6 in the neurotoxic group of 2.9 ± 1.9 years compared with 1.6 ± 2.1 years in controls." Finally, the documented symptoms included "paraesthesia, hyperaesthesia, bone pains, muscle weakness, numbness and fasciculation, most marked on the extremities and predominantly bilateral unless there was a history of previous trauma to the limb."[8]

Very high doses of B_6 have also been reported to produce exacerbation of acne, breast tenderness, or increased milk production (when administered while lactating). However, in reviewing all available data, the FNB concluded: "The data fail to demonstrate a causal association between pyridoxine intake and other endpoints (e.g., dermatological lesions and vitamin B_6 dependency in newborns)."[5] Large doses may theoretically result in increased urinary excretion of other B vitamins, leading to imbalances.

The adverse effects observed have been attributed to intake levels that exceed the liver's capacity to convert pyridoxine to PLP. Consequently, administration of PLP may be advantageous (compared with pyridoxine) when high doses are required for therapeutic efficacy, although this concept has not been evaluated in clinical trials, and monitoring for neurotoxicity would still be prudent.

Adverse Effects Among Specific Populations

Pregnancy and Nursing. Pregnant and lactating women should avoid daily doses of vitamin B_6 greater than 100 mg. Confirmed reports of teratogenicity are lacking.

Infants and Children. Vitamin B_6 is generally not indicated for children under 12 years of age.

Contraindications

Major contraindication is hypersensitivity to vitamin B_6 or any component of a B_6-containing preparation. A yeast-free form is advisable for individuals who are sensitive to yeast.

Precautions and Warnings

A variety of drugs can interact with vitamin B_6, and in some cases, B_6 may significantly reduce the therapeutic activity of the medication.

INTERACTIONS REVIEW

Strategic Considerations

Vitamin B_6 represents a substance that, as a dietary constituent, is widely recommended as beneficial for its physiological function and preventive effects but, as a nutritional supplement or therapeutic agent, is obscured by controversy, prejudice, and partial information. The continuing controversy over the causal role or coincident occurrence and consequent clinical significance of hyperhomocysteinemia in cerebrovascular and cardiovascular disease, and the value of folate, B_6, B_{12}, and B_2 in reducing such risks, has kept this key nutrient in the medical news for several years. However, its broader uses by health care professionals remain largely ignored by conventional practitioners and academic researchers.

Coadministration of vitamin B_6 may counter the pyridoxine-depleting effects of medications such as chemotherapy, methotrexate, theophylline, furosemide and related loop diuretics, isoniazid, cycloserine and other antitubercular agents, and thiosemicarbazide, but especially in individuals and patient populations with high incidences of compromised nutritional status, dysfunctional pharmacogenomic variations, preexisting insufficiency or deficiency, and exacerbating comedication. In most typical situations, coadministration of B_6 usually mitigates adverse effects, with or without marked deficiency, and without impairing drug efficacy.

High-dose oral contraceptives, gentamicin, neomycin, and other aminoglycoside antibiotics can both interfere with the physiological functions of B_6 and deplete available levels. Nevertheless, it appears that administration of pyridoxal 5′-phosphate (PLP, the activated form of vitamin B_6) may not prevent gentamicin-induced nephrotoxicity, even though it may reduce severity of symptoms. Likewise, with haloperidol and related neuroleptic agents, concomitant B_6 can prevent or reduce adverse effects, including drug-induced extrapyramidal symptoms, even in the absence of deficiency signs, but may not enhance therapeutic outcomes.

The situation of antiparkinsonian medications is more complicated because high levels of pyridoxine intake can accelerate peripheral metabolism of levodopa to dopamine, reducing the availability of dopa for central nervous system (CNS)

conversion to dopamine, and impair the therapeutic activity of levodopa. The clinical significance of this effect is usually absent or minimal given the predominant use of low-dose B_6 and the standard practice of combining levodopa with a dopa-decarboxylase inhibitor (DDI), such as carbidopa or benserazide, to reduce excessive peripheral metabolism of levodopa and increase amounts available to the CNS. However, because levodopa acts as a vitamin B_6 antagonist, it can increase the metabolic requirements for pyridoxine. Consequently, coadministration of low-dose vitamin B_6, in the presence of a DDI, can prevent or reverse nutrient depletion and adverse sequelae.

In the case of anticonvulsant medications and related barbiturates, amiodarone, erythropoietin and other erythropoiesis-stimulating agents, or tricyclic antidepressants, the coadministration of B_6 may prevent or mitigate adverse effects and, in some cases, may potentially enhance clinical outcomes. Here the conventional use of vitamin B_6 with antitubercular medications, particularly isoniazid, represents a widely accepted example of integrative principles in action through the dual activity of reducing adverse drug-induced effects and enhancing clinical outcomes.

Although vitamin B_6 is considered an effective preventive or treatment for nausea and vomiting of pregnancy in some women, the combination of doxylamine and pyridoxine may enhance these benefits and is widely used in Canada.

In regard to pharmacokinetic interactions, substances such as tetracycline antibiotics, hydralazine, and penicillamine can bind with vitamin B_6 to form an inactive complex, which is usually excreted in the urine. These interactions tend to decrease drug availability, deplete pyridoxine, and impair B_6-related functions, athough not always to a clinically significant degree.

Somewhat similarly, phenelzine can react with PLP to form a metabolically inactive hydrazone compound and thereby reduce vitamin B_6 levels. Conversely, B_6 coadministration may reverse drug-induced effects such as neuropathy.

The broad, diverse, and profound implications of the adverse effects of antibiotics, in general, on symbiotic intestinal microflora are only beginning to receive the attention of researchers. The secondary adverse effects of such changes on B-vitamin status and inflammatory processes will undoubtedly become the subject of deeper investigation.

The primary adverse effects and risks of vitamin B_6 relate to its classic and well-described overdose symptoms, particularly neuropathies. Although frequently emphasized in the medical literature as a cause for concern, and subsequently restricted as an over-the-counter nutritional supplement in the United Kingdom, the occurrence of such adverse effects is minimal given the large number of self-prescribed users of vitamin B_6.

NUTRIENT-DRUG INTERACTIONS

Amiodarone

Amiodarone (Cordarone).

Effect and Mechanism of Action

Cutaneous photosensitivity, with subsequent increased tendency to sunburn, is one of the more common adverse effects associated with amiodarone, occurring in as many as 70% of patients. In rare cases, extended use of the drug (≥12 months) can cause gradual onset of a slate-gray or violaceous discoloration of sun-exposed sites. Onset of photosensitivity primarily occurs during the second year of therapy, presumably from drug accumulation, and discontinuation of the medication usually leads to resolution of these effects within 2 years.[9-14] Early research by Ferguson et al.[15] indicated that amiodarone has a phototoxic potential against erythrocytes, suggesting a membrane-directed effect. Studying red blood cell hemolysis, Kahn and Fleischaker[16] reported that photo-oxidation of membrane proteins and photoperoxidation of unsaturated fatty acids of membrane lipids could be responsible for this amiodarone-induced damage. Using electron spin resonance (ESR) Guerciolini et al.[17] determined that the triggering mechanism is the creation of a long-lived excited state (triplet state) in the photosensitizer after the absorption of a photon.

Data on the effects of pyridoxine on the phototoxicity of amiodarone are mixed and inconclusive. Cozzani and Jori[18] observed inactivation of L-glutamate decarboxylase from *Escherichia coli*, sensitized by the coenzyme pyridoxal phosphate. Kaufmann[19] reported that coadministration of pyridoxine can "suppress the photosensitivity" of patients with amiodarone-induced photosensitivity. He suggested that amiodarone inhibits melanin formation in the skin via a "hypothetical anti-vitamin-B_6 effect, and that after a latent period of several months, it causes hypersensitivity to solar irradiation."[19] In response, Guerciolini et al.[17] cited the work of Cozzani and Jori, as well as other findings, and proposed that pyridoxine can enhance the phototoxicity of amiodarone, although they specifically declared that this "does not rule out a protective effect of pyridoxine *in vivo*."

Research

In a randomized controlled trial, Mulrow et al.[20] indicated that pyridoxine may exacerbate amiodarone-induced photosensitivity. However, no subsequent research or reports have corroborated this preliminary findings, and the predominant trend in the available data suggests that a protective effect is probable.

Reports

In a letter, Kaufmann[19] described successful amelioration of photosensitivity with coadministration of oral pyridoxine in three patients who had experienced "a marked tendency to sunburn, caused by amiodarone." These patients were able to continue amiodarone treatment, with initial pyridoxine doses ranging from 40 to 300 mg, and maintain good tolerance of solar irradiation with 20 to 40 mg daily doses. He noted that the vitamin B_6 "in no way impaired the desired pharmacological effects of amiodarone" and concluded that the "minimum effective daily dose of pyridoxine remains to be established."[19]

In related research, Ross and Moss[21] reported two cases of erythropoietic protoporphyria in which use of pyridoxine was associated with a marked reduction in photosensitivity without evidence of adverse effects. These patients had been only moderately responsive to beta-carotene and sunscreens.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing amiodarone for extended use as an antiarrhythmic and coronary vasodilator are advised to be watchful for cutaneous toxicity symptoms and consider coadministration of pyridoxine as a preventive or in response to such effects.

Despite the suggestion of potential adverse effects from concomitant intake of amiodarone and vitamin B_6 based on preliminary research, no clinical research or qualified case reports have confirmed such concerns. An initial trial dose of 100 to 200 mg pyridoxine daily for 3 months followed by 20 to 40 mg daily would usually be appropriate. However, both the scientific literature and clinical experience show that the effective dosage levels to prevent or reverse adverse effects of amiodarone vary considerably among individual patients, and that initial dosage levels are typically larger than maintenance doses. Close supervision is warranted during initial higher dose levels because of the possible, but improbable, risk of B_6-induced neuropathy.

Short-term use of amiodarone prophylaxis with major cardiac surgery is unlikely to result in drug accumulation, although administration of vitamin B_6 (as well as folic acid, B_2, and B_{12}) may be indicated in the strategic approach to cardiovascular care in such individuals, at least in relationship to hyperhomocysteinemia.

Anticonvulsant Medications and Related Barbiturates

Evidence: Carbamazepine (Carbatrol, Tegretol), divalproex semisodium, divalproex sodium (Depakote Delayed Release; Depakote ER), fosphenytoin (Cerebyx, Mesantoin), gabapentin (Neurontin), mephenytoin, phenobarbital (phenobarbitone; Luminal, Solfoton), phenytoin (diphenylhydantoin; Dilantin, Phenytek), primidone (Mysoline), valproate sodium (Depacon), valproic acid (Depakene Syrup, Depakene)

Similar properties but evidence lacking for extrapolation: Acetazolamide (Diamox, Diamox Sequels), amobarbital (Amytal), aprobarbital (Alurate), butabarbital (Butisol), butalbital (Fiorinal, Fioricet), clonazepam (Klonopin), clorazepate (Gen-Xene, Tranxene), diazepam (Valium), ethosuximide (Zarontin), ethotoin (Peganone), felbamate (Felbatol), levetiracetam (Keppra), mephobarbital (Mebaral), methohexital (Brevital), methsuximide (Celontin), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), pheneturide (ethylphenacemide), pentobarbital (Nembutal), secobarbital (Seconal), thiopental (Pentothal), tiagabine (Gabitril), topiramate (Topamax), trimethadione (Tridione), zonisamide (Zonegran).

Related but evidence against extrapolation: Lamotrigine (Lamictal).

Effect and Mechanism of Action

High doses of pyridoxine can increase metabolism and decrease serum levels of certain anticonvulsants and barbiturates, specifically phenytoin and phenobarbitone, in some individuals, although not in others. Pyridoxine may accelerate hepatic metabolism of antiepileptic drugs (AEDs) by increasing enzyme activity.[22] However, no mechanism for this reported activity has been confirmed.

Chronic anticonvulsant therapy can exert differing effects on vitamin B_6 metabolism and levels, which may vary for different individuals or different agents or act through diverse mechanisms. Plasma pyridoxal 5′-phosphate (PLP) levels can be significantly decreased with chronic use of carbamazepine and valproic acid, especially in children. Both valproic acid and PLP are strongly protein bound, and valproic acid tends to displace PLP from protective protein-binding sites and induce a deficit in PLP.[23] Conversely, prolonged phenobarbitone and phenytoin (diphenylhydantoin) therapy is associated with fine structural changes in hepatocytes and significantly elevated serum levels of vitamins B_6 and B_{12}.[24]

Pyridoxine-dependent seizures result from an increased genetically derived requirement for the nutrient within the CNS. Researchers have reported that, in some but not all patients, the "binding affinity of glutamate decarboxylase (GAD) to the active form of pyridoxine is low in cases of pyridoxine-dependent seizures (PDS) and that a quantitative imbalance between excitatory (i.e. glutamate) and inhibitory (i.e. gamma-aminobutyric acid, GABA) neurotransmitters could cause refractory seizures."[25] Continued administration of vitamin B_6 in pharmacological doses has contributed to a marked reduction in infantile seizures in some cases. The combination of B_6 and valproic acid or phenobarbital may work synergistically in these patients, even in patients lacking typical indicators of B_6 deficiency.[26]

The reported effect of AEDs on vitamin B_6 levels may be causal to or exacerbating of the elevated levels of homocysteine (Hcy) found in some individuals with seizure disorders using anticonvulsant medications or barbiturates.[27-33] Although Hcy has been used as an experimental convulsant, this hyperhomocysteinemia may be attributable to the underlying disease process, the medication, or both. Enzyme-inducing AEDs, including phenytoin, phenobarbital, and primidone, are associated with numerous adverse effects on B vitamins and Hcy regulation, including low PLP concentrations, decreased folate absorption, decreased plasma folate concentrations, low riboflavin concentrations, and elevated total Hcy concentrations in adults and in children. These effects vary among individuals, with genetic variables, with monotherapy or polytherapy, and with drug mechanisms of action. Coadministration of B_6, folate, and related nutrients, at low to moderate doses, may normalize Hcy levels, particularly in patients receiving AED monotherapy.

Research and Reports

Over more than three decades, researchers have reported numerous possible and proven interactions between vitamin B_6 and related nutrients in individuals undergoing therapy

with anticonvulsants and barbiturates. Evidence indicates the probability of interactions that might adversely affect drug activity and nutrient levels and function, but other research suggests that coadministration under medical supervision may be beneficial in certain patients by mitigating drug-induced hyperhomocysteinemia or enhancing therapeutic response.

Effect on Drug Activity. A study conducted by Hansson and Sillanpaa[22] constitutes the primary, if not singular, published paper mentioned in most accounts of the interactions between vitamin B_6 and the broad range of medications commonly clustered together as antiepileptic drugs. In many instances the details of the report have been misrepresented, exaggerated, or overextended. In this short letter the authors reported marked drops in serum concentrations of phenytoin or phenobarbitone in a small number of patients receiving "long-term multiple antiepileptic medications," most of whom were significantly compromised with "non-progressive brain-damage syndromes in addition to mental retardation and epilepsy." Doses of pyridoxine of 200 or 400 mg daily for 4 weeks elicited the most frequent changes in drug levels, up to 50% in some cases. However, in "several other cases, pyridoxine added to the anticonvulsant treatment did not alter the phenytoin or phenobarbitone concentrations." The most extreme case of decreased serum phenytoin concentrations following administration of 200 mg and then 400 mg per day of pyridoxine involved a 6-year-old girl "during subacute intoxication." The authors noted that the "doses used were arbitrarily chosen," and no attempt was made to determine the "real amount needed per day." Levels of PLP were not assessed. While offering no supportive evidence, the authors suggested that the addition of the pyridoxine may have "increased activity of pyridoxal-phosphate-dependent enzymes involved in the biotransformation (hydroxylation?) of the drugs."[22] Such alterations in drug concentrations could theoretically trigger seizures, but these authors did not relate any such occurrences in their small study. Subsequent research from controlled trials is lacking to confirm these preliminary findings and establish their clinical implications.

Effects on Nutrients and Homocysteine. A broad range of sources present as "incontrovertible" that anticonvulsants decrease the levels and impair the function of numerous key nutrients, including vitamin B_6. Notably, seizures are a known effect of vitamin B_6 deficiency, and certain seizure disorders are specifically pyridoxine dependent. Furthermore, decreased levels of B_6 and related nutrients (folate, B_2, B_{12}) are also strongly associated with elevations in plasma Hcy. Nevertheless, the body of evidence available at this time, although highly suggestive, is mixed and inadequate to confirm or disprove the hypothesis that AEDs promote clinically significant B_6 deficiency or that AED-induced hyperhomocysteinemia inherently results in increased adverse outcomes, or to determine which drugs are more likely to induce such changes and what patient characteristics are associated with increased vulnerability to Hcy elevations and subsequent adverse events. Moreover, some studies have found that serum levels of vitamin B_6 (and/or B_{12}) are elevated in some patients treated with AEDs.

Anticonvulsant medications appear capable of either lowering or elevating levels of vitamin B_6. In a study involving patients with epilepsy on long-term antiepileptic treatment Hagberg et al.[34] found that plasma PLP concentrations were normal in single determinations using tryptophan load tests. However, in patients followed before and during therapy using antiepileptic medication with hydantoin and succinimide (ethosuximide), Reinken[35] observed significant repeated decreases in serum concentrations of PLP. Subsequent research by Reinken[36] suggested an association between anticonvulsant therapy and possible depletion of vitamin B_6 in children.

Haust et al.[23] reported "increased levels of erythrocyte protoporphyrin (EP)" and a "progressive fall in plasma pyridoxal 5'-phosphate (B6-P)" as well as decreased levels of 5-aminolevulinic acid dehydratase (ALA-D) and uroporphyrinogen I synthetase (URO-S) in an epileptic boy undergoing long-term treatment with valproic acid (VPA, 1.3 g/day), CBMZP (0.9 g/day), and folic acid (7.5 mg/day). They administered "pyridoxine HCl (B6-HCl), 87.5 mg/d followed by administration of both B6-HCl and preformed B6-P (50 mg/d each)" and were subsequently able to achieve "the eventual withdrawal of VPA and a net reduction of CBMZP to 450 mg/d." They obtained increases in ALA-D and URO-S before any reduction of CBMZP with pyridoxine hydrochloride alone and then normalization of enzyme levels after "administration of both B6-HCl and B6-P and withdrawal of VPA. During stepwise reduction of VPA, EP remained elevated to values as high as 2.48 μmol/L (upper reference limit, 1.33 μmol/L). Only after permanent withdrawal of VPA did concentrations of EP fall to normal levels." The authors interpreted these findings to suggest "that VPA displaced B6-P from protective protein binding sites" because "both VPA and B6-P are strongly protein-bound," and "that the resulting deficit in B6-P (rather than CBMZP) reduced ALA-D and URO-S activities via primary reduction of ALA-synthetase activity."[23]

In contrast, other researchers have observed apparent elevations of vitamin B_6 levels in individuals being treated with AEDs. Dastur and Dave[24] observed that contrasting pattern when they studied the effects of prolonged anticonvulsant medication in 27 epileptic patients, primarily from low socioeconomic groups, age 15 to 54 years. These subjects had received phenobarbitone (90 mg/day phenobarbital) and diphenylhydantion (300 mg/day phenytoin) regularly for 3 to 32 years and had no history of B-vitamin supplementation. "Besides reduced serum and cerebrospinal fluid (CSF) folate levels, significantly increased levels of total vitamin B_6 in CSF and serum and of vitamin B_{12} in serum were found in patients as compared with normal healthy subjects." Furthermore, despite a lack of "clinical hepatic involvement, liver biopsy performed in nine of twenty-seven patients revealed fine structural changes in hepatocytes suggestive of varying degrees of drug-induced changes. A ramifying network of short, smooth, endoplasmic cisternae with depleted rough endoplasmic reticulum (RER), distended sinusoids with Kupffer cells, dark shrunken hepatocytes with reduced mitochondria, and increased lipofuscin were observed." The authors suggested that these elevations in serum vitamin levels, along with "significant elevation of serum triglycerides and/or cholesterol," might be the result of hepatic damage, specifically "an adaptive response of the liver, a reversible change."[24]

The recycling of folate cofactors depends on vitamin B_6 and riboflavin, and riboflavin is necessary for activating vitamin B_6 to PLP. Plasma Hcy levels tend to be elevated in individuals undergoing long-term AED therapy and may play a role in the increased incidence of atherosclerosis, vascular disease, and stroke observed in this patient population. Although controversial, numerous epidemiological data indicate that chronic

AED administration is associated with various occlusive vascular disease.[37-40]

Numerous researchers have demonstrated that treatment with phenytoin, phenobarbital, and primidone and other enzyme-inducing AEDs is associated with elevated total homocysteine (tHcy) concentrations or decreased plasma folate concentrations in adults and in children.[27,28,41-45] For example, Schwaninger et al.[29] conducted a controlled trial involving 51 consecutive outpatients in an epilepsy clinic receiving stable, individually adjusted AED treatment and 51 gender- and age-matched controls. Assessing plasma concentrations of tHcy and vitamin B_6 and serum levels of vitamin B_{12} and folate in fasted subjects, they observed that "patients and controls differed significantly in concentrations of folate (13.5 ± 1.0 vs. 17.4 ± 0.8 nM) and vitamin B_6 (39.7 ± 3.4 vs. 66.2 ± 7.5 nM), whereas serum concentrations of vitamin B_{12} were similar." Furthermore, they found that plasma Hcy concentration was "significantly increased to 14.7 ± 3.0 microM in patients compared with controls" and that "number of patients with concentrations of >15 microM was significantly higher in the patient group than among controls." The authors noted that these patterns were present with both AED polytherapy and with carbamazepine monotherapy. However, they also cautioned that the observed elevations in homocysteine might be "associated with the disease and not the treatment."[29]

Verrotti et al.[30] evaluated hyperhomocysteinemia in 60 epileptic children (29 females, 31 males), age 14.2 to 17.9 years, receiving sodium valproate (VPA) and carbamazepine (CBZ), monotherapy. They observed "no significant differences in fasting and post-methionine Hcy, plasma PLP, serum folate, erythrocyte folate and serum vitamin B_{12} values between the control group and the two groups of epileptic children" before the initiation of therapy. However, "patients treated with VPA and CBZ showed a significant increase of the plasma concentrations of Hcy when compared to baseline data and controls values" and demonstrated "a significant decrease of serum folate and plasma PLP" after 1 year of therapy. Notably, "serum vitamin B_{12} and erythrocyte folate levels remained in the normal range." The authors suggested two possible interpretations for the increased plasma concentrations of Hcy with prolonged VPA or CBZ treatment. They proposed that remethylation of Hcy to methionine uses 5-methyltetrahydrofolate as a methyl donor and vitamin B_{12} as a cofactor, or "Hcy may conjugate with serine to form cystathionine in a reaction which requires pyridoxal 5'-phosphate . . . as a cofactor."[30] Thus, significantly decreased levels of PLP (P5P) or folate in presence of increased Hcy levels might be predicted with carbamazepine, a potent enzyme inducer, whereas only a small reduction of folate values might be associated with valproate, an AED with less enzyme-inducing activity.[46,47]

Yoo and Hong[41] (1999) and Ono et al.[32] (2002) suggested that a drug-gene interaction involving the C677T variant of the 5,10-methylenetetrahydrofolate reductase (MTHFR) gene might be related to AED-mediated decrease in plasma folate concentrations and an independent predictor of hyperhomocysteinemia in patients receiving AED therapy. Nevertheless, Apeland et al.[48] (2003) reported that patients receiving enzyme-inducing AEDs (carbamazepine monotherapy; phenytoin, phenobarbital, and/or primidone) had low PLP concentrations that were negatively correlated with plasma Hcy concentrations as well as high plasma flavin nucleotide/riboflavin concentration ratios with low riboflavin concentrations. Notably, these patients had higher plasma tHcy concentrations (fasting and after methionine loading) than controls, but such changes in tHcy were not observed in patients who received valproate.

However, more recent research indicates that elevated Hcy levels may not be clinically significant in AED-treated epileptic patients with adequate folate intake. Tamura et al.[31] measured blood concentrations of Hcy, folate, vitamin B_{12}, and PLP and determined MTHFR genotypes in sixty-two patients receiving AED monotherapy (phenytoin, lamotrigine, carbamazepine, or valproate). They reported hyperhomocysteinemia in only 7 (11.4%) of 62 patients overall and 3 (15.0%) of the 20 patients receiving phenytoin. Notably, more than 55% of the patients overall exhibited PLP concentrations below the normal range. In contrast, serum vitamin B_{12} concentrations were elevated in patients treated with valproate. The authors concluded that "hyperhomocysteinemia is not a serious clinical concern in AED-treated epileptic patients" with adequate folate nutriture. However, only "three patients had the homozygous thermolabile genotype of MTHFR; therefore, meaningful statistical analysis [of that particular factor] was not possible in this study."[31] Five years later, Gidal, Tamura, et al.[33] found that 32 weeks of treatment with lamotrigine (mean daily dose, 250 mg) had "no significant effect on concentrations of plasma total homocysteine (tHcy), plasma and red-cell folate and plasma vitamin B_{12}" but that "2070 mg of valproate resulted in a 57% increase in plasma vitamin B_{12} concentrations over the baseline value and a 27% decline in plasma tHcy concentrations." The authors concluded that the data indicated "hyperhomocysteinemia may not be a serious clinical problem" among patients with epilepsy treated with either lamotrigine or valproate.[33] Thus, despite minimal data, it appears that newer AEDs, such as lamotrigine, which lack hepatic enzyme-inducing activity, are less likely to be associated with altered folate concentrations or Hcy metabolism.

Coadministration Benefits. Pyridoxine, alone and in concert with conventional AEDs, has been efficacious in the treatment of certain forms of seizure disorders. Some seizures are pyridoxine dependent, including inborn errors of metabolism, and require an increased intake of the nutrient. Furthermore, low vitamin B_6 is associated with a lowered seizure threshold.[49,50]

In a trial involving 20 patients with infantile spasms, Ito et al.[26] studied the effects of "high doses of vitamin B_6," valproic acid, or both and concluded that the combination of vitamin B_6 and valproic acid was effective and safe in the treatment of infantile spasms (i.e., seizures). Their research found that although vitamin B_6 alone provided some benefit, patients who were given a combination of vitamin B_6 and valproic acid had significantly fewer seizures and better electroencephalogram findings than did the group treated initially with vitamin B_6 alone. However, "vitamin B_6 therapy alone was continued in a single patient who remained seizure-free during the 15-month follow-up period."[26] Pietz et al.[50a] found that 300 mg/kg/day of vitamin B_6 (pyridoxine HCl orally) reduced infantile spasms in 5 of 17 children within the first 2 weeks of treatment, and within 4 weeks, all five patients were free of seizures. "Two patients developed other seizures (partial seizures, etiologically unclear blinking attacks), but no relapse of infantile spasms was observed among the five responders to vitamin B_6." Notably, "no serious adverse reactions were noted," with gastrointestinal symptoms, reversible after dosage reduction, being the primary adverse effects reported. Noting "the life-threatening side effects of treatment with ACTH/corticosteroids or valproate," the authors

concluded by recommending a controlled clinical trial with "high-dose vitamin B_6" to either prove or disprove efficacy.[50a] In a controlled study, Walter-Sack and Klotz[51] found that coadministration of vitamin B_6, 200 mg daily for 4 weeks, resulted in a 45% reduction in phenobarbital blood levels.

Subsequently, Goto et al.[25] investigated binding affinity of glutamate decarboxylase (GAD) in relation to cerebrospinal fluid (CSF) glutamate/GABA concentrations to determine the etiology of pyridoxine-dependent seizures (PDS) and the mechanisms of pyridoxine action in seizure control. They described a patient with PDS whose generalized seizures terminated after intravenous pyridoxine phosphate. This patient's condition had been refractory to conventional antiepileptic medicines and was not accompanied by an elevated CSF glutamate concentration. "No seizure occurred once oral pyridoxine (13.5 mg/Kg per day) was started in combination with phenobarbital sodium (PB, 3.7 mg/Kg per day). The electroencephalogram (EEG) normalized approximately 8 months after pyridoxine was started." Based on these observations, they suggested that pyridoxine-dependent seizure "is not a discrete disease of single etiology in that insufficient activation of GAD may not account for seizure susceptibility in all cases and (2) mechanism(s) of anti-convulsive effect of pyridoxine, at least in some cases, may be independent of GAD activation."[25]

In a rat model, Reyes-Garcia et al.[52] found that B vitamins can enhance the antiallodynic effect of gabapentin (Neurontin). These researchers induced neuropathic pain and measured paw withdrawal in Wistar rats. Tactile allodynia was determined after oral administration of gabapentin (30-300 mg/kg), B vitamins (75-600 mg/kg), or a combination of gabapentin and B vitamins. Their findings "indicate that systemic administration of gabapentin and B vitamins can interact synergistically to reduce neuropathic pain in the rat and suggest the use of this combination to relieve neuropathy in humans."[52]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing AEDs and related barbiturates are advised to be aware that these medications can decrease circulating levels of vitamin B_6 or its activated form, pyridoxal 5'phosphate (PLP), and may cause elevations in plasma homocysteine, with attendant risks. The probability of such adverse effects appears to be significantly greater with enzyme-inducing AEDs (carbamazepine monotherapy; phenytoin, phenobarbital, and/or primidone) than in those receiving valproate or lamotrigine monotherapy; in general, AED polytherapy carries greater risks for this and other adverse effects than does AED monotherapy with any agent. Furthermore, pharmacogenomic variability in metabolism of AEDs and genetic variants affecting folate metabolism, particularly MTHFR polymorphism C677T, can significantly influence drug efficacy and toxicity.

Coadministration of vitamin B_6, usually in combination with folate, vitamin B_{12}, and riboflavin, may be warranted to mitigate adverse effects of these medications on nutrient metabolism as well as increased risks of teratogenicity, hyperhomocysteinemia, and other well-known toxic effects. Moreover, within the context of appropriate clinical management by experienced health care professionals, vitamin B_6 may be indicated as a component of an integrative approach to treatment of seizure disorders, and coadministration with AEDs may enhance the therapeutic response.

Close supervision and regular monitoring is warranted with concomitant use, particularly B_6 doses greater than 200 mg/day. It is particularly important to regularly evaluate serum concentrations of phenytoin and phenobarbital and clinical response in patients receiving concomitant pyridoxine at doses of 200 mg/day or greater. Evidence is lacking to suggest that the small dose levels of vitamin B_6 in typical multivitamins and B-complex formulations might interfere with effective drug dose and therapeutic response.

Chemotherapy

Evidence: Altretamine (hexamethylmelamine, HMM; Hexalen), cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), docetaxel (taxotere), doxorubicin, pegylated liposomal (Caelyx, Doxil, Myocet), fluorouracil (5-FU, Adrucil, Efudex, Efudix, Fluoroplex).
Extrapolated: Other chemotherapeutic agents and combinations.

Effect and Mechanism of Action

Vitamin B_6 may reduce the severity of certain adverse effects associated with several chemotherapeutic agents but may also diminish the therapeutic efficacy of some medications. Palmar-plantar erythrodysesthesia (PPE) syndrome is an adverse effect often associated with antineoplastic treatment using 5-fluorouracil, docetaxel, and doxorubicin HCl liposome injection. This painful condition often constitutes the limiting toxicity of such therapies.[53] Pyridoxine has been shown to mitigate this painful cutaneous toxicity, but the mechanisms of these activities have yet to be elucidated.[54-57] Pyridoxine can reduce altretamine-associated neurotoxicity but may diminish the therapeutic activity of altretamine (hexamethylmelamine) when used in combination with cisplatin.[58] Again, the mechanisms for these effects are as yet unknown.

Research and Reports

Molina, Fabian, et al.[54,56] published two papers on the coadministration of pyridoxine therapy for palmar-plantar erythrodysesthesia associated with low dose continuous infusion 5-fluorouracil (200-300 mg/m^2/day). Their preliminary report (1987) described reversal of PPE, without impairment of therapeutic efficacy, in colon cancer patients receiving 200 mg/m^2/day continuous 5-FU following coadministration of 100 mg/day of pyridoxine.[54] Three years later they published their complete findings showing that concomitant pyridoxine therapy can reverse 5-FU–induced PPE without any adverse effects or interruption of chemotherapy. "Five previously untreated patients who developed PPE received 50 or 150 mg of pyridoxine/day when moderate PPE changes were noted. Reversal of PPE without interruption of the 5-FU was seen in 4/5 patients. Four of these patients who received pyridoxine had responded to 5-FU treatment. No adverse affect of pyridoxine on clinical response was noted."[56]

Vukelja et al.[59] reported two cases in which symptoms of PPE began to resolve within 12 to 24 hours after initiation of pyridoxine, 50 mg three times daily, and continued to improve for several weeks.

In a randomized, double-blind clinical trial involving 41 dogs with non-Hodgkin's lymphoma, Vail et al.[57] compared concomitant pyridoxine therapy to placebo in preventing the development of PPE (PPES) during chemotherapy using Doxil, a doxorubicin-containing pegylated (Stealth) liposome. They observed that the "likelihood of developing serious PPES and having to decrease or discontinue Doxil therapy was 4.2 times (relative risk) greater in placebo group dogs than in pyridoxine group dogs." Although pyridoxine "did not completely abrogate PPES, it occurred later and less dramatically than in placebo-treated dogs and resulted in fewer treatment delays or discontinuations, allowing a higher cumulative dose of Doxil to be received." Furthermore, "no difference was observed in remission rates (71.4 versus 75%) achieved between groups" and a "trend ($P = 0.084$) toward prolongation of remission length was observed in dogs receiving pyridoxine, which was likely attributable to their ability to receive more Doxil without delay or discontinuation." The authors concluded "that pyridoxine is effective in delaying the onset and severity of PPES in this canine model."[57]

Altretamine, also known as hexamethylmelamine (HMM), is a synthetic cytotoxic antineoplastic s-triazine derivative associated with a small but significant occurrence of neurological toxicity. Fabian et al.[60] administered prophylactic pyridoxine or the drug alone in a Phase II trial of hexamethylmelamine (HEX) involving 98 patients with metastatic breast cancer, heavily pretreated with other agents. They reported "a 2% response rate in 89 partially or fully evaluable patients. Seven percent of these patients developed neurologic toxicity which occurred in the HEX-alone group only."[60] Subsequently, Wiernik et al.[58] conducted a trial involving a total of 248 analyzable patients with stages III-IV ovarian epithelial cancer (114 with and 134 without prior chemotherapy) who were randomized to one of four cisplatin (DDP)–hexamethylmelamine (HMM) regimens. Pyridoxine was coadministered at a dose of 300 mg/m^2 orally to evaluate its ability to reduce the neurotoxicity of HMM. Applying multivariate analysis, they identified prior chemotherapy, pyridoxine administration, recent diagnosis, and large tumor size as factors adversely affecting response duration. They concluded: "Although pyridoxine administration significantly reduced neurotoxicity, its adverse effect on response duration suggests that the agent should not be administered with DDP or HMM." The authors recommended further investigation of the "mechanism by which pyridoxine may unfavorably affect response duration."[58]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Pyridoxine coadministration represents a valuable option for adjunctive use with certain forms of chemotherapy (e.g., 5-fluorouracil, docetaxel, doxorubicin HCl liposome injection) as a means of preventing or reducing specific adverse effects, particularly PPE syndrome and neurotoxicity. In contrast, administration of pyridoxine during chemotherapy using altretamine (HMM), especially in conjunction with cisplatin, while potentially beneficial, warrants caution and should be considered as contraindicated in most cases. Safe and effective implementation of any therapeutic strategy combining chemotherapy and pyridoxine requires clinical management within the context of integrative care involving health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics.

The usual dosage of vitamin B_6 ranges from 50 to 100 mg, three times daily orally, and inherently requires close supervision and regular monitoring given the increased risk for pyridoxine toxicity in compromised patients and potential interference with therapeutic efficacy of the concomitant antineoplastic therapy. Physicians and other health care professionals may consider reviewing the potential for such synergistic strategies with appropriate patients and provide referral information to centers specializing in such integrative approaches. The available evidence is limited but suggestive of a broader pattern deserving further research with large, well-designed clinical trials.

Doxylamine

Doxylamine and pyridoxine, combination drug (Bendectin, Diclectin).

Interaction Type and Significance:
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
2. Probable

Evidence Base:
●●● **Consensus**

Effect and Mechanism of Action

Bendectin was introduced in the United States in 1956 by Merrell Dow as medication specifically for nausea and vomiting of pregnancy (NVP). Originally it was formulated as a combination of "doxylamine succinate, an antihistamine with antiemetic properties, dicyclomine hydrochloride, an antispasmodic agent, and pyridoxine hydrochloride (vitamin B_6) to prevent possible deficits during pregnancy and to synergize the antinauseant activity."[61] Based on results of randomized control trials comparing each component alone and in combination versus placebo, dicyclomine hydrochloride was dropped from the formulation in 1976. The standard formulation of Diclectin as of 2003 was 10 mg vitamin B_6 and 10 mg doxylamine per tablet.

Research

Beginning in 1969, allegations and lawsuits appeared, based on single case incidents, claiming possible teratogenic effects of Bendectin resulting in congenital limb deformities. These legal claims were based on limited evidence and failed in court. Several clinical trials and a meta-analysis of 20 studies, including review of Bendectin use by 200,000 patients, failed to demonstrate any causal relationship between Bendectin and congenital malformations.[62-66] Nevertheless, Merrell Dow withdrew Bendectin from the U.S. market and ceased worldwide production in 1983 because of business rather than medical factors, specifically adverse publicity, rising legal costs, and insurance premiums, despite winning their legal battles and continued evidence of safety and efficacy. Diclectin is the only prescription medication recommended for the treatment of NVP available in Canada and is considered the drug of choice.

Physicians have continued to prescribe doxylamine-pyridoxine, and further research has investigated its therapeutic application in subsequent years even as the legal and market history of the medication are cited as a striking example of poorly founded litigation interfering with rational, safe, and effective therapeutics.[67-69] According to a review by Bishai et al.,[70] the "efficacy of the delayed-release combination of doxylamine and pyridoxine (Bendectin, Diclectin) has been shown in several randomized, controlled trials." Nevertheless, a significant discrepancy appears to exist between the reported rate of taking Diclectin and physicians' self-reported prescribing practices for Diclectin.[71] Thus, in 1999, 90% of physicians

reported prescribing Diclectin to their pregnant women with NVP, but only 66% of respondents in a study were actually taking the medication.[72]

In a population-based case-control study, Boneva et al.[73] investigated nausea during pregnancy and congenital heart defects. They found that, overall, early nausea and use of antinausea medication, particularly Bendectin "was associated with a lower risk for congenital heart defects compared with: 1) absence of nausea..., and 2) nausea without medication use." These researchers concluded that these "results suggest that pregnancy hormones and factors or, alternatively, a component of Bendectin (most probably pyridoxine) may be important for normal heart development" and proposed that their "findings outline potential areas for future research on and prevention of congenital heart defects."[73]

Fear of litigation, cautious prescribing, and inadequate communication have all contributed to a pattern of suboptimal dosing in patients treated with doxylamine-pyridoxine. In an observational, prospective study, Atanackovic et al.[74] determined the incidence of adverse maternal and fetal effects and pregnancy outcome in 225 women taking doxylamine-pyridoxine for NVP at the recommended or higher-than-recommended doses. They reported "two pregnancies with major malformation, a finding that is consistent with the rates of birth defects in the general population." They concluded that "the higher than standard dose of Diclectin, when calculated per kg of body weight, does not affect either the incidence of maternal adverse effects or pregnancy outcome." The authors recommended that "if needed, Diclectin can be given at doses higher than four tablets per day to normalize for body weight or optimize efficacy."[74] Likewise, in a clinical trial involving 68 women with moderate to severe NVP, Boskovic et al.[74a] found that "most women (50/68) were receiving 2 tablets a day of Diclectin instead of the recommended dose of 4 tablets a day."

An innovative study suggests that compliance in use of medications such as doxylamine-pyridoxine is influenced by many factors and that cultivation of a strong physician-patient relationship might deserve greater attention. Using survey data from interviews with 59 women recruited from the Motherisk Nausea and Vomiting Helpline, Baggley et al.[72] investigated factors that influence women's decision making on whether to treat NVP pharmacologically. Although all participants were informed that Diclectin was considered safe for use during pregnancy, investigators found that at "a follow-up telephone call, 34% were not using any pharmacologic treatment, and of those who were taking the drug, 26% were using less than the recommended dose." These researchers learned that the rationale offered "for not using the medication were insufficient safety data, preference for non-pharmacologic methods, and being made to feel uncomfortable by the physician." Notably, "of the women who did use Diclectin, the most convincing reassuring information that it was safe to use came from friends and family."[72] Moreover, in a survey conducted by Hollyer et al.,[75] women suffering from NVP expressed significant fear of using "drugs" during pregnancy and stated that they were more comfortable using "natural" and "alternative" therapies to treat NVP and engaged in such self-care with little or no supervision by their medical or naturopathic physicians.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The combination of doxylamine and pyridoxine represents a poignant example of the promises and hazards of drug-nutrient interactions as both therapeutic synergy and medicolegal challenge. The body of evidence indicates that this medication can safely and effectively reduce NVP when used at recommended doses, which at four tablets per day provides 40 mg each of pyridoxine and doxylamine. As mentioned, one study found that the inclusion of vitamin B_6 might actually enhance fetal development and reduce the risk of congenital heart malformations. Most importantly, the tortured history of this innovative medication suggests that the cultivation of a frank, honest, and trusting therapeutic relationship may play a greater role in patient decision making and compliance than any claims of safety or efficacy and attendant scientific "evidence." Further research is warranted, as might be investigation of concomitant use of ginger *(Zingiber officinale)*, which has also been shown to be safe and effective in NVP, with doxylamine and pyridoxine.[76-78]

Effect and Mechanism of Action

Erythropoietin (EPO) therapy increases hemoglobin synthesis, which can decrease erythrocyte pyridoxine status and increase nutritional requirements.

The water-soluble nature and small-to-medium molecular size of vitamin B_6, as well as folic acid and vitamin B_{12}, renders B_6 particularly susceptible to being lost in the dialysate in patients undergoing either peritoneal dialysis or hemodialysis, especially with high-flux dialysis.

Research

It is well known that vitamin B_6 deficiency, from many causes, develops in the majority of patients with chronic renal failure and in patients during various forms of renal replacement therapy. Mydlik, Derzsiova, and Zemberova[79-81] have conducted a series of studies investigating erythrocyte levels of various B vitamins in kidney disease as well as the influence of water, furosemide, and sodium diuresis on the metabolism and urinary excretion of vitamin B_6, oxalic acid, and vitamin C in patients with chronic renal failure. Their most important finding was that erythrocyte vitamin B_6 is consumed by the stimulated hemoglobin synthesis at an increased rate during EPO treatment in hemodialysis patients. In a 1993 study involving 26 patients undergoing regular dialysis treatment (RDT), they investigated the influence of recombinant human erythropoietin (r-HuEPO) on erythrocyte vitamins B_1, B_2, and B_6 by comparing vitamin erythrocyte levels with and without EPO. The non-EPO group received oral pyridoxine 5 mg daily for

9 months while the EPO-treated group received oral pyridoxine 5 mg daily for the first 6 months and 20 mg daily during the following 3 months. They observed a significant elevation in erythrocyte vitamin B_2 levels and a significant decrease in erythrocyte vitamin B_6. However, after administration of the higher doses of pyridoxine (20 mg daily), subjects exhibited "a significant increase in vitamin B_6 and at the end of the 9 months, the values of vitamin B_6 were within the normal range."[79] Further, after establishing that intravenous administration of furosemide (20 mg) leads to an increase of urinary excretion and fraction excretion of vitamin B_6 in patients with chronic renal failure, this research team found that a "daily oral dose of pyridoxine 6 mg was optimal for the patients without erythropoietin (EPO) treatment during the period of 12 months of CAPD." Using pyridoxal 5-phosphate (PLP) as an indirect method of determining erythrocyte vitamin B_6, they concluded that for "prevention of vitamin B_6 deficiency in hemodialysis and CAPD patients we recommend the following doses of pyridoxine: for patients without EPO treatment 5 mg/day, and with EPO treatment 20 mg/day." They also noted that a "favorable effect of pyridoxine 50 mg/day has also been found on several parameters of cellular immunity in hemodialysis patients."[80] Subsequently, they published the results of a 15-month study investigating the influence of erythropoietin on the biochemical parameters of several nutrients. Among these they demonstrated that "erythrocyte vitamin B_6 and folic acid significantly decreased due to erythropoietin treatment." In response, they found that oral administration of vitamin B_6 (20 mg/day) and folic acid (5 mg/week) during the last 3 months positively "influenced the deficiency of erythrocyte vitamin B_6 and folic acid."[81]

In related research, Kasama et al.[82] found the "average *in vivo* PLP clearance for six patients on standard hemodialysis increased by more than 50%... at average blood flows of 375 mL/min" and that levels of "PLP decreased from a baseline of 50 ± 13.8 ng/mL to 24 ± 9.7 ng/mL... after 3 months of HF/HE [high-flux/high-efficiency] treatments; the levels returned to 45 ± 6.4 ng/mL on resumption of standard dialysis treatments." They concluded that HF/HE dialysis "treatments can have a dramatic impact on vitamin B_6 homeostasis." The authors also noted that the use of different types of dialysis membranes and reprocessing in dialysis significantly affected PLP clearance to varying degrees.[82]

In a 1999 review of comprehensive approaches to patients being treated with EPO, Horl[83] summarized the available research regarding pyridoxine and concluded: "Vitamin B_6 requirements are increased during epoetin therapy, and supplementation at a dose of 100-150 mg/week is recommended."

Peripheral polyneuropathy (PPN) is a known adverse effect of nutrient depletion from high-flux hemodialysis. Okada et al.[84] found that vitamin B_6 coadministration can improve PPN in patients with chronic renal failure on high-flux hemodialysis (HD) and r-HuEPO. Their study included 36 patients undergoing chronic high-flux HD and receiving r-HuEPO, 26 of whom suffered from PPN. After determining initial predialysis serum pyridoxal 5'-phosphate (P5P) levels and ranking PPN symptoms in these patients, they administered vitamin B_6 (60 mg/day) prescribed to 14, randomly assigned, and vitamin B_{12} (500 µg/day) to the others. Notably, "predialysis serum P5P levels of HD patients with PPN were not significantly lower than those of matched HD patients without PPN." However, they demonstrated that "supplementation with vitamin B_6 for 4 weeks significantly increased the predialysis level of P5P and dramatically attenuated PPN symptoms compared with initial symptoms." In contrast, no improvement was observed in response to administration of vitamin B_{12}. Thus, coadministration of B_6 was beneficial to HD patients on EPO therapy even though indications of B_6 deficiency, as ascertained by serum levels, were absent.[84]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians administering EPO therapy, particularly in the context of hemodialysis, are advised to consider coadministration of vitamin B_6, 20 to 50 mg/day orally, as well as folic acid, 1 mg/day orally, to prevent or reverse adverse effects on these nutrients and their physiological functions. The body of available evidence strongly suggests that such nutritional support is often appropriate in the absence of overt signs or standard laboratory indications of deficiency. Vitamin B_6 intake at these levels is generally considered safe, although regular monitoring would be judicious in compromised patients, such as those with chronic renal failure. Folic acid is safe at all relevant levels of intake, although care should be taken to rule out concurrent B_{12} deficiency states.

Furosemide and Related Loop Diuretics

Evidence: Furosemide (Lasix).
Extrapolated, based on similar properties: Bumetanide (Bumex), ethacrynic acid (Edecrin), torsemide (Demadex).
See also Erythropoiesis-Stimulating Agents.

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Coadministration Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Furosemide acutely increases urinary excretion of oxalic acid and vitamin B_6 (as well as vitamin C) in individuals with chronic renal failure. This effect could reverse the tendency in uremic patients toward accumulation of oxalic acid, which can result in elevated plasma levels.

Research

Several preliminary human trials have reported increased excretion of vitamin B_6 in individuals administered furosemide and investigated the influence of the nutrient on hyperoxalemia and increased oxalic acid excretion with furosemide.

In a small trial involving eight chronic hemodialysis patients with secondary hyperoxalemia, Balcke et al.[85] observed that pyridoxine administration decreased mean plasma oxalic acid concentration from 149.5 to 99.0 µmol/L within 2 weeks and to 93.8 µmol/L after 4 weeks, with a 46% mean reduction. Notably, the "decrease in plasma oxalic acid levels was most pronounced in patients with the highest pretreatment values." Furthermore, the "two patients who received pyridoxine therapy prior to the beginning of the study had low initial values of plasma oxalic acid concentrations and showed no further decline."[85]

Subsequently, Mydlik et al.[86,87] conducted a series of investigations of the effect of furosemide on urinary excretion of oxalic acid, vitamin C, and vitamin B_6 in patients with chronic renal failure (CRF). In one controlled clinical trial (1998), they observed an increased urinary excretion of oxalic acid, vitamin C, and vitamin B_6 during the first 3 hours after a single intravenous (IV) dose of 20 mg furosemide in a control group and

in CRF patients without dialyzation treatment. They noted that this effect persisted for 6 hours in CRF patients without dialysis. "The authors described a new hitherto unknown positive side-effect of furosemide, i.e. enhanced urinary oxalic acid excretion in the control group and in patients with chronic renal failure without dialyzation treatment and a negative side-effect of furosemide, i.e. increased urinary vitamin B6 excretion in both examined groups." In conclusion, based on these findings, they recommended monitoring of vitamin C and of "vitamin B_6 in plasma during long-term administration of large doses of furosemide to patients with chronic renal failure as deficiency of these vitamins could develop."[86] A year later these researchers published results of another trial in which they compared urinary excretion of vitamin B_6, oxalic acid, and vitamin C in three groups: 15 healthy subjects during maximal water diuresis, 12 patients in polyuric stage of CRF without dialysis treatment receiving a diet high in sodium chloride (15 g/day), and 15 patients in polyuric stage of CRF without dialysis treatment after IV administration of 20 mg furosemide. "Urinary excretion of vitamin B_6, oxalic acid and vitamin C significantly increased during maximal water diuresis while during high intake of sodium chloride the urinary excretions of these substances were not affected." The authors interpreted these results to suggest that "urinary excretion of vitamin B_6, oxalic acid and vitamin C depends on the urinary excretion of water" and to confirm their earlier findings that IV furosemide (20 mg) increases urinary excretion of vitamin B_6, as well as oxalic acid and vitamin C, in patients with CRF.[87]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing furosemide or related loop diuretics are advised to monitor levels of vitamin B_6 and other nutrients and to supplement as indicated, particularly in patients with CRF and on dialysis. Because furosemide also depletes thiamine (vitamin B_1), it is probably best to supplement a B-complex preparation with adequate amounts of B_1 and B_6. Close supervision is warranted with these patients, especially after introducing a new medication or nutrient or changing the dose or combination of any agents.

Gentamicin and Related Aminoglycoside Antibiotics

Evidence: Gentamicin (G-mycin, Garamycin, Jenamicin).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**
≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**
⊕✗ **Bimodal or Variable Interaction, with Professional Management**

Probability: **2. Plausible**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Pyridoxal 5′-phosphate (PLP), the active form of vitamin B_6, readily forms complexes with gentamicin, as well as a wide variety of other potentially toxic substances. This pharmacodynamic interaction interferes with vitamin B_6 metabolism, specifically resulting in a reduction of renal PLP, and has been associated with B_6 depletion. Concomitant vitamin B_6 appears to prevent adverse effects associated with gentamicin, particularly nephrotoxicity, without reducing the drug's efficacy.

Research

A number of animal studies, many conducted by Enriquez, Keniston, Weir, and associates, have documented the adverse effects of gentamicin on vitamin B_6 metabolism and plasma concentrations and the potential benefit of B_6 coadministration. Using a rat model, Keniston et al.[88] found that "PLP protected against GM-induced neuromuscular paralysis and death." Kacew[89] observed that coadministration of PLP for 4 days lowered gentamicin levels in the kidneys and restored renal concentration of PLP to normal levels, but 14 days of PLP administration was required to inhibit gentamicin-induced nephrotoxicity in the rat. Similarly, Weir et al.[90] reported gentamicin administration in rabbits led to a 47% drop in plasma PLP levels. Their findings also suggested that "gentamicin interferes with vitamin B_6 metabolism, but that vitamin B_6 status does not affect levels of gentamicin." Subsequently, these researchers demonstrated that vitamin B_6 can protect against the nephrotoxicity of gentamicin in rabbits, particularly acute tubular necrosis. They did note, however, the possibility of interstitial nephritis with intramuscular injection of high doses of vitamin B_6 based on the reaction of one rabbit.[91] In other research using a rat model, Smetana et al.[92] determined that a "specific concentration of pyridoxal-5-phosphate may be necessary to provide protection against all manifestations of aminoglycoside-induced renal damage." Ali and Bashir[93] found that although PLP, at the doses used, "reduced significantly the severity of some of the manifestations of nephrotoxicity,... [it] was ineffective in completely preventing the development of nephrotoxicity."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing gentamicin or other aminoglycoside antibiotics are advised to consider the potential benefit of coadministering vitamin B_6 to mitigate adverse effects, particularly aminoglycoside-induced nephrotoxicity. The available evidence is consistent in its findings but limited by the exclusive presence of animal studies. The research reviewed suggests that such concomitant intake is unlikely to impair the therapeutic efficacy of the medication. Clinical trials are warranted to investigate patterns of adverse effects and interactions and to determine guidelines for a safe and effective clinical response.

Haloperidol and Other Neuroleptic Agents

Evidence: Haloperidol (Haldol).
Extrapolated, based on similar properties: Chlorpromazine (Largactil, Thorazine), clozapine (Clozaril), fluphenazine (Modecate, Permitil, Prolixin, Prolixin Decanoate, Prolixin Enanthate), prochlorperazine (Compazine, Stemetil).
Similar properties but evidence lacking for extrapolation: Atypical antipsychotics: Aripiprazole (Abilify, Abilitat), clozapine (Clozaril), olanzapine (Symbyax, Zyprexa), quetiapine (Seroquel), risperidone (Risperdal), ziprasidone (Geodon).

Effect and Mechanism of Action

Tardive dyskinesia and parkinsonian symptoms, especially dystonia, are adverse effects typically associated with haloperidol and other psychotropic medications. Neuroleptic agents are known to induce oxidative stress, and lipid peroxidation appears to play a central role in the development of tardive dyskinesia.[94]

Vitamin B_6 plays a key role in the synthesis of serotonin, dopamine, norepinephrine, and gamma-aminobutyric acid (GABA) and other neurotransmitters, all of which have been proposed to be involved in the development of tardive dyskinesia. Concomitant administration of vitamin B_6 can prevent or reduce drug-induced tardive dyskinesia and related extrapyramidal symptoms but may not enhance therapeutic outcomes in the management of psychotic symptoms in schizophrenic and schizoaffective patients.[95]

Research

Miodownik, Lerner, Kotler, and colleagues have conducted a series of small trials investigating the use of vitamin B_6 in the treatment of neuroleptic-induced tardive dyskinesia (TD). They have consistently found that coadministration or addition of vitamin B_6 (100-500 mg/day) produced "clinically significant (greater than 30%) improvement on measures of involuntary movement" using the Abnormal Involuntary Movement Scale (AIMS), Barnes Akathisia Rating Scale (BARS), the Simpson-Angus Scale (SAS), and the Extrapyramidal Symptom Rating Scale (ESRS). In some cases, they also measured "clinically significant improvement" on the Brief Psychiatric Rating Scale (BPRS).[95,96] Subsequently, they reported "significant improvement in tardive dyskinesia and parkinsonian symptoms" in a double-blind crossover trial lasting 9 weeks involving 15 patients, suffering from schizophrenia and schizoaffective disorder with positive psychotic symptoms and TD, who received up to 400 mg vitamin B_6 daily. However, their findings in this study "did not show any therapeutic effect on psychotic symptoms from vitamin B_6 added to antipsychotic agents," which patients received on a constant basis.[97] None of the patients in these trials experienced adverse effects attributable to vitamin B_6. The emerging pattern in these studies strongly suggested that continued research is warranted to clarify the relationship between vitamin B_6 and TD.

These investigators examined whether basal levels of vitamin B_6 might serve as a predictive marker to distinguish which patients might be more vulnerable to such adverse reactions. In one paper they reported that, "although patients in the TD group were exposed to neuroleptic drugs for significantly longer periods of time, there were no differences" in serum PLP levels between the treated group and controls. Based on these findings, they concluded that "reports of the effectiveness of vitamin B_6 supplementation in the treatment of TD could therefore be explained by the assumption that central nervous system or intracellular vitamin B_6 levels, which are involved in the pathogenesis of TD, are not the same as vitamin B_6 peripheral serum levels."[98] Likewise, in a subsequent paper, these researchers noted that there was "no direct correlation between pathological symptoms and the serum baseline level of vitamin B_6 nor its level during the treatment."[97] Thus, the available evidence has yet to reach a level of clarity to confirm that these medications consistently deplete functional levels of vitamin B_6 or to clarify the mechanisms involved in the adverse effects or their mitigation.

In a review of research on the treatment of TD and tardive dystonia, Simpson[99] wrote: "Tardive dyskinesia not only may be painful and disfiguring, but it also predicts poor outcome in patients with schizophrenia .... The best treatment for tardive dyskinesia and dystonia is prevention, which is a function of medication choice."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing neuroleptic drugs known to cause TD and related adverse extrapyramidal effects are advised to coadminister vitamin B_6 to prevent or reduce the occurrence and severity of such reactions. The pyridoxine levels, 200 to 400 mg daily, indicated in such situations are potentially capable of causing adverse neurological effects (primarily peripheral neuropathy) and require close supervision and regular monitoring.

Hydralazine

Hydralazine (hydralazine hydrochloride, 1-hydrazinophthalazine monohydrochloride; Apresoline); combination drugs: hydralazine and hydrochlorothiazide (Apresazide); hydralazine and isosorbide dinitrate (BiDil).

Nutrient Depletion
Probability: **4. Plausible** to **2. Probable**
Evidence Base: ○ **Preliminary**

Drug Interference
Probability: **4. Plausible** to **2. Probable**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Hydralazine and vitamin B_6 can bind to form a complex that is excreted in the urine, potentially decreasing available levels of hydralazine, depleting pyridoxine, and impairing B_6-related functions.[100] Thus, hydralazine acts as pyridoxine antagonist, inhibits a number of enzymes requiring pyridoxal as a cofactor, and may increase vitamin B_6 requirements and/or cause

anemia, peripheral neuritis, or other B_6-deficiency neuropathies.[101] Conversely, such pharmacokinetic interaction with vitamin B_6 may decrease the therapeutic effectiveness of hydralazine.[102]

Reports and Research

Pyridoxine-deficiency neuropathy and other B_6-related adverse effects due to hydralazine have been well known for decades, beginning with a case report published in 1965 by Raskin and Fishman.[101] Rumsby and Shepherd[100] elaborated on the effect of hydralazine (as well as penicillamine and phenelzine) on the function of PLP. Subsequently, Vidrio[102] investigated the potential role of hydralazine's interaction with pyridoxal as the basis for its hypotensive effect. He noted that the "drug interacts with pyridoxal and can produce B_6 deficiency; it also inhibits a number of enzymes requiring pyridoxal as a cofactor, but there is no apparent relation between its enzymatic and blood pressure effects." Using a rat model, he found that "responses to hydralazine were diminished by pyridoxine and [that the] inhibitory effect of pyridoxine was absent when rats were pretreated with the calcium antagonists verapamil or cinnarizine. Hydralazine hypotension in anesthetized rats was also reduced by pyridoxal pretreatment." The author concluded that these findings "suggest that at least part of hydralazine-induced hypotension may be related to interaction with pyridoxal, possibly through interference with an effect of the vitamer on calcium and/or sodium transport into vascular smooth muscle," a "vitamer" being one or more related chemical substances that fulfill the same specific vitamin function.[102]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing hydralazine, alone or as a combination drug, are advised to consider potential benefits of vitamin B_6 coadministration. Such concomitant pyridoxine therapy may prevent or reverse adverse effects due to the known actions of the medication. Furthermore, an integrative approach combining these agents may be potentially valuable strategically (preventing hyperhomocysteinemia and potentially reducing the risk of vascular disease, stroke, and dementia). Nevertheless, evidence from well-designed and adequately powered human trials is lacking to confirm need for and benefit of vitamin B_6 coadministration or increased pyridoxine intake. Further research is warranted, although it may be a low priority because of the substantially decreased clinical usage of this agent over the past few decades.

In cases where pyridoxine is indicated, certain precautions are recommended. A daily dose of 50 to 100 mg vitamin B_6 would be typical in such usage. At such levels the probability of adverse effects from the nutrient are low, but extended use could theoretically cause toxicity symptoms in some individuals. Attention to the potential for adverse effects is judicious within the usual schedule of supervision and monitoring for individuals being treated for hypertension. Caution patients to separate intake of hydralazine and vitamin B_6 by at least 2 hours to minimize the risk of any diminished bioavailability of either agent due to complex formation.

Isoniazid, Rifampin, and Related Antitubercular Agents

Cycloserine (Seromycin), ethambutol (Myambutol), ethionamide (2-ethylthioisonicotinamide; Trecator SC), isoniazid (isonicotinic acid hydrazide; INH, Laniazid, Nydrazid), pyrazinamide (PZA; Tebrazid), rifampicin (Rifadin, Rifadin IV); combination drugs: isoniazid and rifampicin (Rifamate, Rimactane); isoniazid, pyrazinamide and rifampicin (Rifater).

Effect and Mechanism of Action

A number of antitubercular drugs exert significant adverse effects on normal metabolism and function of vitamin B_6, as well as folate and niacin/niacinamide. These medications are occasionally used as single agents but are more often administered in multidrug regimens for the treatment of tuberculosis (TB), especially in patients co-infected with HIV.

Isoniazid is a hydrazine derivative and pyridoxine antagonist that reacts with PLP to form a metabolically inactive hydrazone, inactivating PLP, and thereby producing a functional vitamin B_6 deficiency. Thus, isoniazid can interfere with the normal activity of pyridoxine through competitive inhibition, usually in a dose-dependent manner.[103] These effects may lead to anemia or peripheral neuropathies.[104-108] Further, the ingestion of toxic amounts of isoniazid, as little as 1.5 g in adults, can cause increasingly severe adverse effects, with refractory seizures, profound metabolic acidosis, coma, and occasionally death at doses larger than 30 mg/kg.[109] Intravenous pyridoxine is considered the specific antidote for acute isoniazid neurotoxicity and is often used before or along with hemodialysis.[110,111]

Cycloserine acts as a pyridoxine antagonist by forming a metabolically inactive oxime. The resulting impairment of vitamin B_6 availability reduces blood levels of pyridoxine and may lead to anemia or peripheral neuropathies.[112,113] However, seizures, which may accompany cycloserine administration, may result from pyridoxine depletion associated with the underlying tubercular infection rather from a direct pyridoxine antagonism by the drug.[114]

Both isoniazid and cycloserine inhibit human erythrocyte pyridoxal kinase using pyridoxal, but not pyridoxamine, as substrate and can react with pyridoxal or PLP to form covalent complexes. Kinetic studies suggest that the observed pyridoxal kinase inhibition resulted from these formed complexes.[115]

Ethionamide, an antileprosy drug sometimes used in combination with other agents for treating multidrug-resistant tuberculosis, may also increase vitamin B_6 requirements.[106]

Research

The action of isoniazid and related antitubercular drugs as pyridoxine antagonists is generally agreed on, and the efficacy of pyridoxine in countering the toxic effects of isoniazid is well established.[107,113] Nevertheless, the issue of whether all patients are vulnerable to clinically significant adverse effects with typical clinical practice involving antitubercular drugs has been contentious, and the benefits of routine vitamin B_6 coadministration have been the subject of long-standing controversy.

The relationship between the toxic effects of isoniazid and other anti-TB drugs and their interference with vitamin B_6 has been developed over many years and is regarded as consensus.[107,112,113,116] Several early studies by Polish researchers focused on the effects of isoniazid and ethionamide on pyridoxine metabolism in children and the use of the tryptophan test as an assay for determining pyridoxine levels.[106,117,118] However, an investigation of the effect of cycloserine on pyridoxine-dependent metabolism in TB by Nair et al.[114] indicated that the pathological processes of TB itself contributed significantly to B_6 depletion. Measuring urinary tryptophan metabolites, they observed an "abnormally high level of xanthurenic acid excretion in untreated patients," which they interpreted to suggest "a decreased availability of pyridoxal phosphate related to the disease process. Although plasma cycloserine levels were kept high once therapy began, xanthurenic acid excretion before and after tryptophan load became progressively more normal as symptoms diminished." The authors noted that "throughout the study, no significant changes in 5-hydroxyindoleacetic acid excretion were observed" and suggested that "the convulsions which may sometimes accompany cycloserine administration are not due to a direct pyridoxine antagonism by the drug."[114]

In a 1980 review of the scientific literature on pyridoxine administration during isoniazid therapy, Snider[103] reported on the frequency of INH-induced neuropathy in various studies and identified population groups at relatively high risk of developing this often-serious complication. He reported that pyridoxine administration "during isoniazid (INH) therapy is necessary in some patients to prevent the development of peripheral neuropathy" and concluded that the "routine use of pyridoxine supplementation to prevent peripheral neuropathy in high risk populations is recommended."[103] Subsequently, Mbala et al.[119] conducted a prospective, single-blind, placebo-controlled, randomized trial involving 85 children with TB in Zaire. These researchers observed no occurrences of "neurological or neuropsychiatric disorder ... in the two groups during the 6 months of the treatment and 3 months after the treatment" and interpreted their findings to "suggest that the vitamin B_6 supplementation of isoniazid therapy is unnecessary in childhood TB."[119] However, in a review article on recognition and management of isoniazid overdose, also published in 1998, Romero and Kuczler[109] cautioned that "physicians must be aware of its potentially fatal effects." They concluded: "Given in gram-per-gram amounts of the isoniazid ingested, pyridoxine (vitamin B_6) usually eliminates seizure activity and helps to correct the patient's metabolic acidosis. Isoniazid toxicity should be suspected in any patient who presents with refractory seizures and metabolic acidosis." Overall, the consensus within the scientific literature indicates that patient characteristics are more significant than drug toxicity alone in determining the need for nutrient coadministration, but that pyridoxine is effective in the prevention and treatment of isoniazid toxicity.[120]

The coadministration of isoniazid (INH) and pyridoxine has frequently been used in the treatment of HIV-infected individuals at risk for or diagnosed with TB. Chaisson[121] and Gordin et al.[122] reported the findings of two independent clinical trials that compared combinations of isoniazid with pyridoxine or rifampin and pyrazinamide (PZA) in the treatment of patients with HIV and latent TB infections and prevention of active TB development. INH/pyridoxine given for 6 to 12 months was effective in preventing TB in dually infected adults. However, treatment with rifampin and pyrazinamide, dosed either daily or twice weekly, required only 2 months of treatment to prevent TB effectively in such patients.

In 1957, McCune et al.[123] conducted in vivo animal studies suggesting that administration of high doses of vitamin B_6 can interfere with the effect of isoniazid and indicating that the appearance of this isoniazid antagonism might be delayed. Evidence from human trials is lacking to confirm this proposed interaction or to determine its clinical significance and frequency.

Reports

Haden[105] described a case of pyridoxine-responsive sideroblastic anemia due to antitubercular drugs.

Brent et al.[111] reported "three cases of obtundation secondary to isoniazid overdose that was immediately reversed by intravenous pyridoxine." Status epilepticus seizures were stopped by IV pyridoxine administration in two of these cases; although the patients remained comatose for prolonged periods, the comas were immediately reversed by the administration of additional pyridoxine. In the third case, isoniazid-induced lethargy was treated by IV pyridoxine on presentation, and the patient responded with immediate reversal of lethargy. The authors concluded that pyridoxine is "effective in treating not only isoniazid-induced seizures, but also the mental status changes associated with this overdose" and noted that the "dose required to induce awakening may be higher than that required to control seizures."[111]

Chan[124] described a case in which administration of 10 mg/day of pyridoxine was ineffective in reversing isoniazid-induced psychosis. This dose is relatively low, and the author suggested that a larger dose, such as 50 mg/day, might have been necessary.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians treating individuals with latent or active TB are advised to consider coadministration of vitamin B_6 (as well as folic acid and niacinamde) to prevent or counter potential adverse drug effects, particularly development of nutrient deficiency and peripheral neuropathy, associated with isoniazid and related antitubercular drugs. Assessment of risk for nutrient deficiency at the initiation of treatment and testing of nutrient levels during therapy may be warranted in certain cases.

Although almost certain to occur to some degree, clinically significant adverse effects on vitamin B_6 levels and related functions are generally considered improbable in most healthy, well-nourished patients with typical dosage levels, such as isoniazid (INH) 5 mg/kg. However, these medications can pose significant risks in major segments of the populations at greatest risk of exposure to TB, latent TB infection, or active TB: impoverished, malnourished, or homeless persons; IV drug users; HIV-positive individuals; institutionalized elderly persons; and those with severe illness or compromised health. Risks of adverse drug effects are also heightened in patients who are pregnant, have underlying seizure disorders, or are at significant risk for the development of peripheral neuropathy

due to comorbid conditions such as malnutrition, diabetes, HIV infection, alcoholism, or uremia.

In cases where pyridoxine is indicated certain precautions are recommended. Although no recommended dosage level has been established, a daily dose of 50 mg vitamin B_6 is typical in such cases. At such low levels, the probability of adverse effects from the nutrient are low. Monitoring for potential adverse effects from pyridoxine is nevertheless recommended as judicious because extended use, especially with 'higher doses,' could theoretically cause toxicity in some individuals. However, the intercurrent development of peripheral neuropathy while receiving antitubercular treatment could also reflect inadequate pyridoxine status, so there may be a role for laboratory evaluation in such cases.

The general toxicity, and hepatotoxicity in particular, associated with antitubercular medications remains a significant clinical concern in all patients. In particular, isoniazid, pyrazinamide, and rifampin are not recommended for patients with a history of liver toxicity related to any antitubercular medication or underlying liver disease and should be used with caution in patients being treated with other potentially hepatotoxic drugs. Close supervision and regular monitoring are recommended, beginning with complete blood count, platelet levels, and hepatic functioning at the initiation of treatment, then monthly in patients being treated with single-drug therapy (INH or rifampin) and at 2, 4, 6, and 8 weeks for those receiving both rifampin and pyrazinamide for 2 months. Clinical monitoring consists of a detailed review for possible signs and symptoms of drug-induced hepatitis or other adverse effects, including rash, fever, fatigue, nausea, vomiting, jaundice, right upper quadrant abdominal pain, and paresthesias. Refractory seizures and metabolic acidosis are hallmarks of toxicity and demand urgent intervention with parenteral pyridoxine. "Isoniazid should be discontinued in symptomatic patients whose serum aminotransferases are more than three times normal and in asymptomatic patients whose aminotransferases are more than five times normal."[125]

Levodopa, Carbidopa, Benserazide, and Related Antiparkinsonian Medications

Carbidopa (Lodosyn), levodopa (L-dopa; Dopar, Larodopa); combination drugs: levodopa and benserazide (co-beneldopa; Madopar); levodopa and carbidopa (Atamet, Parcopa, Sinemet, Sinemet CR); levodopa, carbidopa, and entacapone (Stalevo).

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Pyridoxal 5'-phosphate (PLP) acts as a cofactor in the conversion of levodopa to dopamine. Levodopa acts as a vitamin B_6 antagonist, and increased levels can increase the metabolic requirements for pyridoxine. Concomitant low-dose vitamin B_6 can prevent or reverse nutrient depletion and adverse sequelae. Conversely, excessive levels of pyridoxine can accelerate peripheral metabolism of levodopa to dopamine (in the gastrointestinal tract). Because levodopa can cross the blood-brain barrier, but dopamine cannot, this reduces the levodopa normally available to the central nervous system (CNS).[126-128] Pyridoxine may also alter levodopa metabolism by Schiff-base formation.[129] Consequently, high levels of pyridoxine intake can reduce the availability of dopa for conversion to dopamine and impair the therapeutic activity of levodopa administered in the treatment of Parkinson's disease. However, combining a DDI such as carbidopa or benserazide with levodopa reduces excessive metabolism of levodopa and increases amounts available to the CNS. Under such conditions, pyridoxine, even at high concentrations, is usually unlikely to affect peripheral metabolism, diminish serum levels of levodopa, or impair drug activity.[130]

Reports and Research

Stockley[129] characterizes the interaction between pyridoxine and levodopa as "clinically important, well documented and well established." Beginning in 1969, a series of reports described and studies consistently demonstrated a pattern of predictable interaction between these two agents. Barham Carter[131] noted that in "the treatment of parkinsonism with levodopa it is often necessary to prescribe drugs to combat the nausea which occasionally occurs," and thus vitamin B_6 had been recommended or self-prescribed based on its potential benefit in alleviating nausea and vomiting. In a much-cited paper, Duvoisin et al.[132] delineated the basic pattern of the antagonism of the effects of levodopa by pyridoxine. They reported that high-dose pyridoxine, 750 to 1000 mg daily, produced a noticeable reduction in the effects of levodopa within 24 hours, and that the effects of the medication were completely abolished within 3 to 4 days. Further, the effects of levodopa were reduced or abolished with daily doses of 50 to 100 mg per day. Notably, daily intake of 5 to 10 mg pyridoxine was associated with an increase in the signs and symptoms of parkinsonism in eight of ten patients. Leon et al.[133] observed a 66% reduction in plasma levodopa levels and exacerbation of Parkinson's disease symptoms in three of four patients administered 50 mg pyridoxine daily concomitantly. A number of other reports and trials confirmed these findings, and a consensus was established by the early 1970s.[126,134-139]

Yahr and Duvoisin[140] determined that a pyridoxine-deficient diet is probably unnecessary to achieve avoidance of B_6-induced impairment of levodopa therapy and might result in pyridoxine deficiency and subsequent adverse effects.

A DDI such as carbidopa or benserazide can neutralize the interactions between pyridoxine and levodopa but may also deplete vitamin B_6. In 1972, Papavasiliou et al.[130] demonstrated the lack of adverse effect from pyridoxine when carbidopa was coadministered with levodopa in a paper describing the "potentiation of central effects with a peripheral inhibitor." In a small study involving six patients on chronic levodopa treatment for Parkinson's disease, Mars[141] reported that mean levodopa plasma levels dropped by from 356 to 109 ng/mL (70%), when 50 mg pyridoxine was coadministered with 250 mg levodopa. In contrast, with levodopa-carbidopa, their mean plasma levels of

levodopa increased to 845 ng/mL, almost threefold. Moreover, with 50 mg pyridoxine, mean plasma levels of levodopa rose slightly higher, to 891 ng/mL, although the plasma integrated area was 22% less than that observed with levodopa-carbidopa. However, in a series of in vitro, animal, and preliminary human studies, Bender et al.[142-145] suggested that benserazide and carbidopa may cause vitamin B_6 depletion by forming hydrazones, inhibiting enzymes in the oxidative pathway of tryptophan metabolism and of nicotinamide nucleotide synthesis, and depleting niacin. Overall, most researchers and reviewers concur that use of a DDI with levodopa functionally eliminates the probability of a clinically significant impairment of levodopa's activity and therapeutic efficacy from vitamin B_6 at typical dosage levels. Thus, Stockley's review concludes that "even in the presence of large amounts of pyridoxine, the peripheral metabolism remains unaffected and the serum levels of levodopa are virtually unaffected."[129] Research is lacking to substantiate the suggestion that either carbidopa or benserazide may deplete vitamin B_6 levels to a greater degree than levodopa alone.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing levodopa as monotherapy need to caution patients to avoid unplanned consumption of vitamin B_6 above typical dietary levels, such as greater than 5 mg per day, particularly in the form of B_6 supplements or multivitamins containing pyridoxine. Such contraindications are generally considered moot for individuals administered levodopa combined with a DDI such as carbidopa or benserazide, as is currently the standard of care in Parkinson's disease management.

Concomitant administration of low-dose vitamin B_6, 5 to 10 mg per day, may be appropriate to prevent drug-induced pyridoxine deficiency and attendant adverse effects from levodopa or benserazide and carbidopa. Vitamin B_6 may also be indicated in certain patients for prevention of dietary deficiencies, reduction of known health risks, and treatment of comorbid conditions. Close supervision and regular monitoring for decreased effects of levodopa are necessary in individuals for whom vitamin B_6 is indicated during levodopa therapy (without a DDI), particularly since the dose required to counter nutrient depletion overlaps with the lowest dose observed to reduce the therapeutic effect of non-DDI protected levodopa. Limited pyridoxine intake may also be prudent in patients being treated with levodopa-carbidopa (Sinemet) or levodopa-benserazide (Madopar) because these agents may deplete B_6, but high doses of pyridoxine might potentially overwhelm the protective effect of the DDI. In general, any vitamin B_6 intake should be accompanied by food, a meal, or a light snack at bedtime, and separated from levodopa by at least 2 hours. Patients should be advised that increased parkinsonian symptoms would be the typical warning sign of diminished drug activity.

Effect and Mechanism of Action

Because inflammation causes tissue-specific depletion of vitamin B_6, individuals with rheumatoid arthritis (RA) more likely tend be to be vitamin B_6 depleted, and abnormal vitamin B_6 status is associated with severity of symptoms in patients with RA.[146-149]

Homocysteine (Hcy) can be metabolized by various pathways, requiring various enzymes, such as methylenetetrahydrofolate reductase and cystathionine beta-synthase, involving reactions that require vitamin B_6 and folate as cofactors. Specifically, vitamin B_6 is involved in the formation of cystathionine from Hcy and is critical to the formation of 5,10-methylenetetrahydrofolate from tetrahydrofolate. Folate and vitamin B_{12} are involved in the remethylation of Hcy to methionine via a B_{12}-dependent reaction. Elevated plasma total homocysteine (tHcy) has been established as an independent risk factor for cerebrovascular disease, coronary atherosclerosis, peripheral vascular disease, and thrombosis, although the preventive and therapeutic benefit of nutritional therapies to lower Hcy remains to be conclusively demonstrated.

Methotrexate interferes with folate and Hcy metabolism. Both methotrexate and decreased vitamin B_6 (and folate) status can contribute to increased Hcy levels and attendant risks. Coadministration of vitamin B_6, usually with folic acid or activated folic acid, may lower Hcy levels and reduce related pathogenic processes and risks.

Research

A series of studies by Chiang, Selhub, Roubenoff, and colleagues have focused on the relationship between inflammatory processes, RA, and vitamin B_6 status. They reported that plasma pyridoxal 5'-phosphate (PLP) concentration is correlated with functional vitamin B_6 indices in patients with RA and marginal vitamin B_6 status.[150] Furthermore, they have documented strong and consistent associations between vitamin B_6 status and several indicators of inflammation in patients with RA and observed an inverse correlation between circulating vitamin B_6 levels and clinical indicators, including the disability score, length of morning stiffness, degree of pain, and biochemical markers, including erythrocyte sedimentation rate and C-reactive protein levels.[146,148] Based on these findings, they have suggested that "such strong associations imply that impaired vitamin B_6 status in these patients results from inflammation."[149] Subsequently, they conducted a cross-sectional, case-controlled, human clinical trial in parallel with experiments in an animal model of inflammation to investigate whether inflammation directly alters vitamin B_6 tissue contents and its excretion in vivo. Human subjects with RA had low plasma PLP levels compared with healthy control subjects, but normal erythrocyte PLP and urinary 4-pyridoxic acid excretion. Adjuvant arthritis induced in rats did not affect 4-pyridoxic acid excretion or muscle storage of PLP, but did result in significantly lower PLP levels in circulation and in liver during inflammation. Based on these findings, they concluded that the "low plasma pyridoxal 5'-phosphate levels seen in inflammation are unlikely to be due to insufficient intake or excessive vitamin B_6 excretion," but that instead, "inflammation induced a tissue-specific depletion of vitamin B_6" as vitamin B_6 coenzymes are removed from the circulation to meet the higher demands of certain tissues during inflammation.[149]

Although the issue of methotrexate's adverse effect on the role of vitamin B_6 in regulating Hcy is largely agreed on, the clinical significance of Hcy, and its possible elevation by methotrexate, remains contentious. In a 12-month, randomized double-blind trial involving 62 patients with RA and elevated Hcy (≥12 μmol/L), Yxfeldt et al.[151] investigated the effects of administering a combination of vitamins B_6, B_{12}, and folic acid on Hcy levels and analyzed the relationship between Hcy levels and inflammatory variables, and/or methotrexate (MTX) treatment. The Hcy level decreased significantly in the subjects treated with B vitamins compared with those given placebo. Furthermore, in a "multiple regression model there was an association between the alteration in Hcy level over 0-12 months and MTX treatment, as well as the alteration in CRP, adjusted for B-vitamin treatment." The authors concluded that Hcy levels in patients with RA can be reduced by treatment with B vitamins, and that Hcy levels were related to markers of inflammation and MTX treatment.[151] However, in a pilot study involving 17 juvenile idiopathic arthritis patients and 17 age-matched and gender-matched healthy children, Huemer et al.[152] found that hyperhomocysteinemia in children with juvenile idiopathic arthritis is not influenced by MTX treatment and folic acid supplementation.

Further research is warranted to determine the degree to which methotrexate adversely influences levels and functions of vitamin B_6, as well as factors influencing interpatient variability, alterations in Hcy status, the influence of B-vitamin supplementation on clinical outcomes, and appropriate nutrient support levels when administration is indicated.

No sources reviewed cited any evidence to suggest that concurrent administration of vitamin B_6, alone or in a multivitamin formulation, might impair the therapeutic efficacy of methotrexate in the treatment of RA or other nononcological applications.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians administering methotrexate for the treatment of rheumatoid arthritis are advised to consider coadministration of vitamin B_6 (50-100 mg/day) with folic acid, possibly in an activated form, such as folinic acid or 5-L-methyl folate. Such concurrent nutrient support may be effective in countering adverse effects of methotrexate on the physiological activities of vitamin B_6, particularly in the regulation of Hcy, and thereby may reduce related risks of vascular disease. More broadly, individuals with RA are more likely to be nutritionally compromised and benefit from enhanced intake of all key nutrients. Similarly, evaluation of patients for genetic polymorphisms, such as MTHFR 677 C→T, are potentially at greater risk for adverse effects from medications that impair folate metabolism or deplete folate levels.

Neomycin

Neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
5. **Improbable** or
2. Probable (depending on duration)

Evidence Base:
○ **Preliminary** (though generally regarded as ●●● **Consensus**)

Effect and Mechanism of Action

Neomycin may impair the activity of vitamin B_6.[153] Furthermore, oral neomycin can decrease absorption or increase elimination of folic acid and other nutrients, including beta-carotene, calcium, carbohydrates, fats, iron, magnesium, potassium, sodium, vitamin A, vitamin B_{12}, vitamin D, and vitamin K.[116,154] The effects on folic acid and vitamin B_{12}, in particular, can adversely effect vitamin B_6 activity. These effects increase with time in long-term neomycin therapy and can be most significant in the elderly population.[155]

Research

Faloon et al.[156] (1966) documented the adverse effects of neomycin on intestinal absorption of nutrients. Hardison and Rosenberg[157] further elucidated the effect of neomycin on bile salt metabolism and fat digestion in humans. Subsequently, the adverse effects of neomycin on nutrient status were explored extensively in the pioneering work of Daphne A. Roe, MD (1923–1993), of Cornell University, Division of Nutritional Sciences, through publications such as "Drug-Induced Nutritional Deficiencies" (1976). As such, this interaction has largely passed into the "consensus" of the literature documenting adverse drug effects and drug-induced nutrient depletions, without passing through the stages of published case reports, human trials, reviews, etc., which constitute the emerging standard within the scientific literature of drug-nutrient interactions. Further research may be warranted.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing a course of oral neomycin lasting more than a few days are advised to coadminister a multivitamin-mineral supplement containing vitamin B_6. Depletion is improbable with short-term use of oral neomycin associated with surgery or perioperative care. A course of probiotic flora is also appropriate following broad-spectrum antibiotics to restore normal gut ecology.

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCept 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).

Effect and Mechanism of Action

Oral contraceptives (OCs) are associated with many symptoms suggestive of a drug-induced vitamin B_6 deficiency and in many ways parallel to postpartum depression or gestational diabetes mellitus. However, these iatrogenic elevations of exogenous estrogen and progestins may contribute to adverse effects such as depression, premenstrual syndrome, and dysglycemia by altering the metabolism and functions of vitamin B_6 more than by directly affecting vitamin B_6 status or causing B_6 deficiency.

Oral contraceptives can interfere in the role that vitamin B_6 plays in facilitating the tryptophan conversion to niacinamide pathway. PLP-dependent enzymes are required in the conversion of L-tryptophan to 5-hydroxytryptamine and L-tyrosine to norepinephrine, as well as synthesis of dopamine, norepinephrine, and gamma-aminobutyric acid (GABA). OCs appear to impair 5-hydroxtryptamine (5-HT, serotonin) formation through interference with 5-hydroxytryptophan decarboxylase and thus contribute to depression due to resulting decreased brain levels of serotonin. Tryptophan dioxygenase is a glucocorticoid-induced enzyme. Elevating concentrations of pyridoxal phosphate by administering pyridoxine reduces synthesis and activity of this enzyme and attenuates the response to glucocorticoid hormones. The resulting reduction in the oxidative metabolism of tryptophan increases the amount of tryptophan available for CNS synthesis of serotonin. OCs with higher estrogen dose increase levels of estrogen metabolites that inhibit kynureninase. The resulting increased tissue and blood concentrations of xanthurenic acid tend to complex with insulin to form a relatively inactive complex and thus impair glucose tolerance.[158,159] Furthermore, abnormal metabolism of tryptophan results not only from induced hepatic tryptophan oxygenase, but also from specific changes in the activity of enzymes beyond kynurenine in the pathway of tryptophan metabolism.[160-162] Additionally, abnormally elevated excretion of tryptophan metabolites could potentially cause some degree of true vitamin B_6 deficiency.[163-165]

Coadministration of vitamin B_6 may ameliorate symptoms associated with OCs, especially when exacerbated in women with compromised nutritional status or other susceptibility factors.[158,166-169] Concomitant pyridoxine support during OC use appears to enable a direct effect of pyridoxal phosphate in inducing tryptophan oxidase and thereby corrects the effects of OCs on tryptophan metabolism, even in the absence of preexisting deficiency.[6,164,170-178] Vitamin B_6 can also enhance glucose tolerance by activating apokynureninase or kynureninase that has been inactivated by undergoing transamination.[179] The dosage of estrogen in the OC formulation appears to influence the probability of adverse effects, at least in some women.

In regard to adverse cardiovascular effects of OCs and other exogenous estrogens, it is noteworthy that pyridoxal 5-phosphate is essential for the metabolism of the atherogenic amino acid homocysteine.

Nutritional requirements for riboflavin may also be higher in OC users because this nutrient is needed to oxidize pyridoxine phosphate to pyridoxal phosphate. Conversely, niacin requirements may be reduced due to alterations in tryptophan metabolism.

Research

A large body of scientific literature indicates that OCs can cause a number of adverse effects in some women, but the issue of whether vitamin B_6 is necessary and should be routinely coadministered to prevent such outcomes remains contentious and unresolved.

Several studies have documented that vitamin B_6 deficiency is relatively common in the U.S. and U.K. population, and numerous papers have reported that reduced levels of vitamin B_6 in women using OCs compared with the general population.[2-4,180-184]

The impact of OCs on vitamin B_6 itself and its functions and the clinical benefit of concurrent pyridoxine administration have been the subject of debate for decades. Variations in the choice of subjects, characteristics of controls, composition and dosage levels of the OCs tested, measures of B_6 status used, adverse effects assessed, and duration of the trials have all contributed to inconsistencies in findings and mixed conclusions.

Over more than a decade the research team of Adams, Rose, Wynn, and colleagues conducted a series of investigations into the relationship between OCs and vitamin B_6. In 1972 they reported that 80% of women taking OCs had abnormal tryptophan metabolism and about 20% demonstrated evidence for absolute deficiency of the nutrient.[185] Reviewing the scientific literature on the subject in early 1973, they wrote that "the altered excretion of tryptophan metabolites observed in women on o.c. is similar to that found in nutritional vitamin-B_6 deficiency, and is corrected by the administration of vitamin B_6. Vitamin B_6 requirements may be further increased by the effect of oestrogen conjugates competitively inhibiting pyridoxal phosphate."[158,160,186-188] Then, in a double-blind, crossover trial involving 22 women "whose depression was thought on clinical grounds to be due to o.c. administration," these researchers observed positive clinical responses on depression with coadministration of B_6 (20 mg twice daily), but notably only in that half of subjects with "absolute vitamin-B_6 deficiency." They suggested that other factors needed to be considered for depression in the other half of depressed women and mentioned insufficient substrate due to tryptophan deficiency as a possible factor.[161] Their continued investigation into the effects of excretion of metabolites after oral loading doses of L-kynurenine led them to conclude that OC use "does not generally change the requirement for vitamin B_6 but rather produces a specific change in activity of enzymes beyond kynurenine in the pathway of tryptophan metabolism."[162] Bennink and Schreurs[181] reported that "vitamin B_6 blood concentration was not affected" in 50 women using combined OCs but also observed that "OCs increased XA [xanthurenic acid] excretion after tryptophan administration in 80% of the users." Amatayakul et al.[159] reported no significant adverse effects on B_6 status but also noted that "urinary xanthurenic acid excretion ... [was] significantly increased by OC treatment, although this excessive XA excretion was adequately corrected with 18 mg of daily vitamin B-6 supplementation." In a 6-month trial, van der Vange et al.[189] investigated the effect of seven low-dose OC preparations, containing equivalent amounts of ethinyl estradiol but different amounts and types of progestagen, on vitamin B_6 status in 55 women. They observed increases in erythrocyte glutamic-oxaloacetic transaminase (EGOT)

activity, a pyridoxal phosphate–dependent enzyme, and the calculated total EGOT activity after 6 months' treatment, but no changes were observed in the degree of in vitro stimulation, considered a more reliable parameter. Plasma PLP levels initially decreased during the first 3 months of treatment, but levels returned to normal after 6 months. Based on these findings, the authors concluded that "the low-dose preparations investigated in this study have no any adverse effects on vitamin B_6 status."[189] Notably, several studies used women with intrauterine devices (IUDs) as controls; a questionable proposition given the emerging understanding of the impact of inflammation on B_6 status.

Massé et al.[190] investigated the effects of a low-dose triphasic OC preparation (30 µg estrogen) in 14 young female subjects (and nine matched controls). They found that short-term OC use did not demonstrably alter PLP levels in plasma and erythrocytes in the majority of women with adequate dietary intake. Although by employing two methods of assessment, "only one case (7%) of deficiency due to OC was evidenced, ... a disturbance in vitamin B_6 metabolism was detected. PL levels in both blood components have increased steadily and did not subside to pretreatment values at the end of the experiment." They concluded by suggesting that "the single use of the PLP vitamer can be misleading as demonstrated by other investigators" and suggested the need to explore B_6 status further by evaluating "the other aldehydic form of vitamin B_6, to fully establish and comprehend hormone-induced adverse effects on this metabolism, particularly those of progesterone/progestin that have not yet been explored."[190] In a double blind, placebo-controlled trial, involving women taking low-dose OCs, Villegas-Salas et al.[191] reported no significant benefit in the prevention of adverse effects, such as nausea, vomiting, dizziness, depression, and irritability, from coadministration of up to 150 mg of pyridoxine daily.

In overview, the trend in the scientific literature indicates that OCs, especially in lower dose forms, usually do not directly deplete vitamin B_6 in most women, but may increase such risk or may be more likely to contribute to related adverse effects in those with higher B_6 requirements or compromised nutritional intake. However, most but not all researchers have found that OCs present a significant risk of altering several normal physiological pathways that involve B_6-dependent enzymes, and that in many cases, coadministration of pyridoxine, even in low doses, can prevent or reverse adverse effects related to hyperestrogenism, such as depression, dysglycemia, and premenstrual syndrome. Evidence is lacking at this time to support routine supplementation because of the inconsistencies in methodology and limited nature of the available research. Further investigation through well-designed and adequately powered long-term clinical trials is warranted to evaluate which patients are at greatest risk for adverse effects and most likely to benefit from nutrient support, as well as clinical parameters for determining dosage levels and concomitant nutrients indicated for optimal intervention.

The issue of whether or not concomitant vitamin B_6 supplementation might be beneficial or necessary in women taking OCs remains unresolved, but the discussion of adverse effects from such coadministration has usually not extended beyond the usual medical caution regarding dose-related pyridoxine toxicity. However, in 1973, Adams et al.[161] suggested that women with low daily protein consumption might be at increased risk for adverse effects with pyridoxine supplementation due to an increase in amino acid catabolism as a result of excess pyridoxine relative to protein intake. Throughout the lengthy but limited history of human research on this issue, the absence of incidents of actual adverse effects attributable to excess pyridoxine intake is notable, especially given the loud warnings so often voiced regarding the potential risk of nutrient-induced toxicity.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing OCs are advised to assess the patient's individual physiological characteristics, medical history, and nutritional status to determine the probability of an adverse reaction to the treatment. Based on such evaluation, or in response to a patient's expressed concern, it would then be appropriate to consider whether vitamin B_6 coadministration might reduce the risk and severity of potential adverse effects of the exogenous hormones, including effects on pyridoxine levels and function and increased incidence and severity of depression, dysglycemia, premenstrual syndrome, and disorders associated with elevated estrogen levels. Although the typical supplemental dose for pyridoxine in such situations is 10 to 75 mg per day, higher levels in the range of 100 to 400 mg per day may be indicated for short periods in cases where individual preventive and therapeutic requirements may be greater. Adverse effects from pyridoxine are improbable at lower doses, but such higher doses of vitamin B_6 may have significant risk of causing adverse effects and require caution, professional supervision, and regular monitoring, even for short periods. In cases where broader nutritional deficits are apparent, the administration of a multivitamin-mineral formulation may be more appropriate than a narrower pyridoxine prescription.

The tryptophan load test may provide a functional assessment of vitamin B_6 status and its influence upon tryptophan metabolism. With depression, as with any complex condition, the presence of OCs is unlikely to constitute the sole cause, or even be the decisive factor. Nevertheless, in certain cases, OCs may be inappropriate because of adverse effects.

Experienced practitioners of natural therapies frequently coadminister a range of agents to women who seek care for presumed adverse effects from OCs. Botanical preparations such chasteberry *(Vitex agnus castus)*, dandelion root *(Taraxacum officinale)*, fringetree root and bark *(Chionanthus virginicus)*, dong quai *(Angelica sinensis)*, burdock root *(Arctium lappa)*, and wild yam root *(Dioscorea villosa)* have an extensive history of traditional usage and are administered clinically to enhance hepatic conjugation of estrogen, facilitate hormonal self-regulatory systems, and mitigate hyperestrogenism. Calcium, magnesium, evening primrose oil, riboflavin, folic acid, ascorbic acid, vitamin B_{12}, and vitamin E may also be beneficial for some women, particularly with preexisting insufficiency or drug-induced deficiency. Individualized assessment and an evolving therapeutic response involving collaboration of health care professionals trained and experienced in the various therapeutic modalities applied are usually essential to successful clinical outcomes.

Penicillamine

Penicillamine (D-Penicillamine; Cuprimine, Depen).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
5. **Improbable** or
3. Probable

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Penicillamine can act as a pyridoxine antagonist by reacting with pyridoxal 5'-phosphate (PLP) to form a metabolically inactive thiazolidine. This pharmacokinetic interaction can increase vitamin B_6 excretion, reduce its physiological activity, and over time, increase the risk for a functional pyridoxine deficiency.[100,192,193] Vitamin B_6 may be coadministered to counteract potential adverse effects, such as anemia and peripheral neuritis.[194]

The formation of a metabolically inactive chelate could also potentially interfere with penicillamine to impair its therapeutic action to a clinically significant degree.

Separating the intake of two substances that tend to bind by several hours usually minimizes such interaction in the gastrointestinal tract.

Research

The long-term use of penicillamine may increase pyridoxine requirements. Pyridoxine administration can prevent or reverse pyridoxine deficiency as a result of this interaction.

Vitamin B_6 can act as an anticonvulsant. Conversely, seizures have been induced by D,L-penicillamine and other vitamin B_6 antagonists, such as hydrazine and thiosemicarbazide. Using a mouse model, Abe and Matsuda observed that "the onset of convulsions induced by these convulsants coincides with the fall in GABA [gamma-aminobutyric acid] content and GAD [glutamic acid decarboxylase] activity in the mesencephalon area, and in contrast, the cessation of the convulsions by PN [pyridoxine] supplement coincides with the recovery in both the parameters."[195,196]

Researchers have noted an interrelationship between zinc and magnesium depletion and pyridoxine inactivation in autoimmune complications and other adverse effects associated with D-penicillamine.[197,198] In a trial involving 144 rheumatoid arthritis patients treated with penicillamine (125-1000 mg/day), Rumsby and Shepherd[199] found that 17% developed vitamin B_6 deficiency. However, clinical signs of deficiency were absent, using in vitro measurement of percentage stimulation of erythrocyte alanine aminotransferase (ALT) on addition of an excess of PLP to the blood sample. The investigators observed significantly higher unstimulated activity of PLP, a PLP-dependent apoenzyme, in penicillamine-treated subjects than in controls, as expected if ALT were deficient in its PLP coenzyme. Furthermore, they reported less marked in vitro ALT stimulation by PLP at intermediate penicillamine dosage levels, compared to controls. Such a pattern suggests that a pyridoxine deficiency is more likely in the early stages of penicillamine therapy, after which some degree of recovery might occur, and that lasting or recurrent deficiency is more likely in individuals later administered higher doses of the drug. These findings suggest that, barring clinical signs of pyridoxine deficiency, most patients are unlikely to require pyridoxine coadministration, unless they have a history of poor nutritional intake or other compromising factors.[199] Nevertheless, Rothschild[194] and other investigators have suggested that coadministration of vitamin B_6, in daily doses as high as 50 mg, may be indicated. Other methods of assessing B_6 deficiency might also be sensitive, such as measuring urinary xanthurenic acid excretion following an oral tryptophan load test.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing penicillamine are advised that coadministration of vitamin B_6 may be prudent. Substantive evidence is lacking to confirm the need for and benefit of routine B_6 coadministration, and further research with well-designed and adequately powered clinical trials may be warranted. Nevertheless, the available evidence is adequately consistent from both pharmacological and clinical perspectives to warrant preventive measures, especially since they carry minimal risk. Monitoring of pyridoxine status may be warranted with chronic penicillamine therapy.

Certain patients are at higher risk for adverse reactions to penicillamine and risk of complications from pyridoxine deficiency. In particular, because of their dietary restrictions, individuals with Wilson's disease and cystinuria being treated with penicillamine would benefit from 25 mg of pyridoxine daily during therapy. Likewise, a daily supplement of pyridoxine is also indicated for patients with rheumatoid arthritis whose nutrition is impaired. In general, individuals taking penicillamine for any reason should supplement with the relatively small dose of 5 to 20 mg of vitamin B_6 daily. However, given the potential for binding, oral intake should be separated by at least 2 hours.

Phenelzine and Related Monoamine Oxidase (MAO) Inhibitors

Evidence: Phenelzine (Nardil), tranylcypromine (Parnate).
Extrapolated, based on similar properties, as MAO-A inhibitors: Isocarboxazid (Marplan), procarbazine (Matulane).
Similar properties but evidence indicating no or reduced interaction effects: Moclobemide (Aurorix, Manerix), pargyline (Eutonyl).
Not supported by extrapolation from evidence (MAO-B inhibitors): selegiline (deprenyl, L-deprenil, L-deprenyl; Atapryl, Carbex, Eldepryl, Jumex, Movergan, Selpak).
See also Selegiline in Theoretical, Speculative, and Preliminary Interactions Research.

Interaction Type and Significance
◈◈ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**
⊕✗ **Bimodal or Variable Interaction, with Professional Management**
≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
2. **Probable** or
3. Possible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

The conversion of tryptophan to serotonin (5-hydroxytryptamine) is catalyzed by a PLP-dependent enzyme. Dopamine, norepinephrine, and gamma-aminobutyric acid (GABA) are other neurotransmitters synthesized using PLP-dependent enzymes. CNS serotonin is metabolized by monoamine oxidase (MAO) to 5-hydroxyindoleacetic acid (5-HIAA). MAO inhibitors elevate serotonin concentrations (along with other monoamine neurotransmitters, e.g., dopamine) by inhibiting such metabolic breakdown of the monoamine neurotransmitters.

Phenelzine can act as a pyridoxine antagonist by reacting with PLP to form a metabolically inactive hydrazone

compound and reduce blood levels of vitamin B_6. Isoniazid and hydralazine, agents with chemical structures similar to phenelzine, are known to cause vitamin B_6 deficiency.[107,108,178] Thus, these drugs can decrease pyridoxine status and induce peripheral neuropathy, carpal tunnel syndrome, and other conditions associated with pyridoxine deficiency.

Reports and Research

There have been numerous reports of vitamin B_6 deficiency and subsequent adverse effects associated with long-term MAO inhibitor therapy. Despite the well-documented adverse effects of similar substances, there has been no definitive confirmation of the consistent but anecdotal and preliminary evidence involving phenelzine and related agents. Likewise, substantive evidence is lacking to prove benefit from nutrient coadministration. Research through well-designed and adequately powered clinical trials is warranted.

Harrison et al.[200] published a case report of carpal tunnel syndrome associated with tranylcypromine in 1983. That same year, Heller and Friedman[201] reported a case of pyridoxine deficiency and peripheral neuropathy associated with long-term phenelzine therapy. In 1984, Demers et al.[202] reported pyridoxine deficiency in two young men treated with phenelzine. "Alleviation of symptoms possibly associated with this deficiency and correction of subnormal serum B_6 levels occurred with the administration of pyridoxine." Several years later, Goodheart et al.[203] described the cases of two patients in whom clinical and electrophysiological findings confirmed sensorimotor peripheral neuropathy associated with phenelzine therapy. "Symptoms were predominantly sensory, and improvement occurred after withdrawal of phenelzine. Electrophysiologic findings were consistent with an axonal process."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing phenelzine or related MAO inhibitors need to be alert to the possibility of this potential adverse interaction and instruct patients to eat a diet providing adequate amounts of vitamin B_6. Preventive coadministration of vitamin B_6 supplements may be warranted, especially in patients with compromised nutritional intake or comorbid conditions or medications that might also impair B_6 status. Many providers trained and experienced in nutritional therapeutics routinely advise patients treated with these medications to supplement with vitamin B_6, usually at moderate levels, such as 25 to 50 mg per day. Alternately, nutrient support can be initiated if untoward reactions occur during phenelzine treatment suggestive of B_6 deficiency. Monitoring of pyridoxine status may be warranted with chronic MAO inhibitor therapy. Although the MAO inhibitors are much less frequently used in the modern era of psychopharmacology, because of their well-known and dangerous interactions with medications such as meperidine, propoxyphene, and dextromethorphan, as well as food components such as tyramine, they remain important agents for certain patients with bipolar or unipolar depression who respond to none of the other classes of agents.

Tetracycline Antibiotics

Demeclocycline (Declomycin), doxycycline (Atridox, Doryx, Doxy, Monodox, Periostat, Vibramycin, Vibra-Tabs), minocycline (Dynacin, Minocin, Vectrin), oxytetracycline (Terramycin), tetracycline (Achromycin, Actisite, Sumycin, Topicycline; combination drugs: Deteclo, Helidac).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **4. Plausible**

Evidence Base: **◉ Emerging**

Effect and Mechanism of Action

Oral B vitamin intake, including pyridoxine, may interfere with tetracycline pharmacokinetics, impairing absorption and bioavailability. Such an interaction would also impair bioavailability of the nutrient(s). Tetracyclines can also increase vitamin B_6 urinary excretion.

Research

Omray and Varma[204] demonstrated that oral administration of a formulation containing vitamin B complex and vitamin C could impair absorption and reduce bioavailability of tetracycline through pharmacokinetic interference.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing tetracycline or related antibiotic medications can prudently advise patients regularly supplementing with vitamin B_6, alone or within a B-complex vitamin formulation, to take such supplements and the medication at least 4 hours apart. Although depletion of vitamin B_6 (from simultaneous intake and binding) may not have clinical significance with short-term use of tetracycline, individuals using the drug longer than 2 weeks may benefit from supplementation. A moderate supplemental dose of pyridoxine is usually in the range of 20 to 25 mg per day, easily obtained through most multivitamin formulas. Sustained use of higher doses of B_6 can potentially result in adverse effects and warrants supervision. Significant dietary sources of vitamin B_6 include bananas, lentils, potatoes, raisin bran, turkey, and tuna.

Prudence suggests that individuals treated with tetracyclines or other broad-spectrum antibiotics for an extended time be administered a course of probiotic flora for an equivalent duration to restore intestinal microbiota. Short-term use of tetracyclines may not lead to clinically significant alterations in the gastrointestinal ecology.

Theophylline/Aminophylline

Theophylline/aminophylline (Phyllocontin, Slo-Bid, Slo-Phyllin, Theo-24, Theo-Bid, Theocron, Theo-Dur, Theolair, Truphylline, Uni-Dur, Uniphyl); combination drug: ephedrine, guaifenesin, and theophylline (Primatene Dual Action).

Similar properties but evidence lacking for extrapolation: Dyphylline (Dilor, Lufyllin), oxytriphylline (Choledyl).

Effect and Mechanism of Action

Theophylline is a potent noncompetitive inhibitor of pyridoxal kinase, the enzyme needed to convert vitamin B_6 to its active form, pyridoxal 5′-phosphate (PLP) and therefore is a pyridoxine antagonist.[115,205] Theophylline also, paradoxically, induces pyridoxal kinase synthesis, thus speeding up pyridoxine metabolism, depending on the balance of these two opposing actions, and sometimes may result in depressed circulating PLP concentrations and body stores of pyridoxine, even though circulating pyridoxal levels may remain unchanged.[90,206-210] The resultant deficit of PLP results in multiple decreased B_6-dependent enzyme activities, including GABA synthesis, and can increase the risk of seizures, hand tremor, and other adverse CNS effects of theophylline.[209] Thus, theophylline may increase intake requirements for vitamin B_6, whereas concomitant pyridoxine or pyridoxal administration may normalize B_6 levels and reduce many theophylline-induced adverse effects without impairing the therapeutic activity of theophylline.[211,212] This beneficial effect may result, at least in part, from the modulating effect of pyridoxine and that of theophylline on catecholamine release.[213,214] Moreover, pyridoxine levels tend to be low in many asthmatic individuals, and its administration may play an important role in the treatment of asthma.

Research

A large number of animal experiments and human trials consistently demonstrate an adverse effect of theophylline on vitamin B_6 levels and functions that can be clinically significant, a high probability of benefit from administration of B_6 in some form, and a lack of adverse effects from concurrent intake.

Delport, Ubbink, Bartel, and colleagues at the University of Pretoria researched the interaction between theophylline and vitamin B_6 in many studies over several years.[215] In a 1988 study they reported that plasma PLP concentrations were significantly lower in a group of 28 asthmatic women, compared to 33 controls, although plasma pyridoxal levels were not different between the two groups. When they administered theophylline to 17 volunteers, they observed "large reductions in plasma pyridoxal-5′-phosphate levels, while plasma pyridoxal levels and urinary 4-pyridoxic acid excretion were unaffected by theophylline therapy."[205] The following year, in a 4-week placebo-controlled, double-blind trial involving apparently healthy young men, they demonstrated that theophylline greatly reduced serum vitamin B_6 levels and erythrocyte PLP levels through noncompetitive inhibition of erythrocyte pyridoxal kinase, and that both plasma PLP levels and the tryptophan load test normalized after 1 week of pyridoxine vitamin B_6 (10 mg/day).[206] Subsequently, they "demonstrated a significant correlation . . . between drug plasma levels and erythrocyte pyridoxal kinase activities" and showed that vitamin B_6 coadministration produced "a four-fold increase in circulating pyridoxal 5′-phosphate levels."[211]

Other researchers have also reported depression of vitamin B_6 levels due to theophylline. Using a rabbit model, Weir et al.[90] observed that administration of "theophylline preparations intraperitoneally (aminophylline) or orally (sustained-release anhydrous theophylline) resulted in a 47% depression of plasma pyridoxal 5′-phosphate (PLP) levels. The 87% increase in PLP with pyridoxine administration was only 18% when aminophylline was also given." They described the mechanism of the theophylline-B_6 interaction as "obscure" but noted that the "ethylenediamine in some theophylline preparations binds directly to PLP, potentially increasing the less direct theophylline effect." Furthermore, they cautioned that "pyridoxine supplementation resulted in higher average PLP levels but did not prevent death in animals with profoundly low PLP levels."[90] In a study of 26 asthmatic children, Shimizu et al.[216] found a depression of serum PLP levels existed in asthmatic children treated with theophylline compared with those not receiving theophylline; thus a "significant negative correlation between the serum levels of PLP and theophylline was demonstrated in the subjects." Oral administration of 200 mg of theophylline (Theo-Dur) to five children with asthma significantly depressed serum PLP levels 4 hours after the drug intake, whereas theophylline did not affect serum pyridoxal levels. Subsequently, this team of researchers studied 23 asthmatic children, 7 to 15 years old, including 16 patients who were treated with slow-release theophylline and seven patients not receiving any theophylline preparation. They evaluated steady-state serum theophylline and vitamin A, B_1, B_2, B_6, B_{12}, and C levels and demonstrated a "significant negative correlation between theophylline and circulating levels of vitamin B_6," with serum vitamin B_6 levels lowered by 40% in the children treated with slow-release theophylline for more than a year.[217] Likewise, Tanaka et al.[209] investigated the effect of sustained-release theophylline preparations on circulating vitamin B_6 concentrations in 26 children with asthma and determined that "serum PL and PLP concentrations in children within theophylline therapeutic ranges (5 to 15 micrograms/mL) were significantly lower than those with theophylline concentrations of less than 5 micrograms/mL." Martinez de Haas et al.[218] studied 141 adults and found that both geriatric and nongeriatric patients with chronic obstructive pulmonary disease being treated with theophylline exhibited markedly higher prevalence of subnormal vitamin B_6 status, as measured by PLP in whole blood, than did those not being treated with theophylline. Notably, 70% of the 40 chronic obstructive pulmonary disease (COPD) patients not treated with theophylline and 56% of the 84 geriatric non-COPD patients also had a subnormal vitamin B_6 status, suggesting a rather high baseline B_6 deficiency rate in the geriatric population.

The adverse effects of theophylline on the nervous system are well documented, with theophylline-induced seizures, in particular, being widely recognized for their significant morbidity and mortality given their recalcitrance to treatment. Glenn et al.[208] investigated the relationship between depressed plasma PLP levels and decreased GABA synthesis with theophylline treatment and the occurrence of seizures in experiments involving mice and rabbits. They observed that pyridoxine administration significantly decreased rates of seizure and death, and that "serum theophylline levels and plasma PLP levels showed significant negative correlation prior to pyridoxine infusion." They noted that "all six rabbits

developed abnormal EEGs during theophylline infusion and all six rabbit EEG patterns returned to baseline during treatment with pyridoxine."[208] In a randomized, double-blind, placebo-controlled, crossover study, the South African researchers previously discussed administered theophylline to 15 young, healthy adults daily for 4 weeks, at a dosage level adjusted to produce plasma levels of 10 mg/L (10 μg/mL), combined with either placebo or 15 mg pyridoxal hydrochloride. Theophylline-induced tremor was greatly reduced with vitamin B_6 administration "after a single dose of theophylline and a similar but nonsignificant trend was observed with repeated doses." Subjects treated with pyridoxine also reported lessening of faint feeling, trembling, irritability, and other adverse effects on nervous system function associated with theophylline. Nevertheless, a variety of psychomotor and electrophysiological tests and self-report questionnaires failed to confirm any significant response differences within these parameters.[219] More recently, Seto et al.[210] measured serum pyridoxal (PAL) levels in children with bronchial asthma treated with theophylline to study whether a theophylline-related seizure is caused by a decrease in serum vitamin B_6. They determined that the serum PAL levels of 31 asthmatic children treated with theophylline were significantly lower than those of 21 control subjects. Moreover, three of the four subjects who experienced a seizure, with or without fever, exhibited low PAL levels within 24 hours.

None of the studies reviewed reported an adverse interaction with concurrent intake of pyridoxal and theophylline.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing theophylline or related medications for extended periods are advised to coadminister vitamin B_6, 10 to 25 mg per day, to prevent or reverse adverse effects of the medication. The probability of drug-induced adverse effects is relatively high, especially at higher doses, given for extended periods, and in patients at higher risk for compromised nutritional status (e.g., children, elderly, chronically ill), and the safety profile of vitamin B6 at these conservative dosage levels is quite strong. Supervision and monitoring are appropriate, particularly in unstable patients or those undergoing a change in medication or dosage.

Tricyclic Antidepressants (TCAs)

Evidence: Nortriptyline (Aventyl, Pamelor).

Similar properties but evidence lacking for extrapolation: Amitriptyline (Elavil), combination drug: amitriptyline and perphenazine (Etrafon, Triavil, Triptazine), amoxapine (Asendin), clomipramine (Anafranil), desipramine (Norpramin, Pertofrane), doxepin (Adapin, Sinequan), imipramine (Janimine, Tofranil), protriptyline (Vivactil), trimipramine (Surmontil).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

The conversion of tryptophan to serotonin (5-hydroxytryptamine) is catalyzed by a PLP-dependent enzyme. Dopamine, norepinephrine, and GABA are other neurotransmitters synthesized using PLP-dependent enzymes.

Research

Vitamin B_6 deficiency may be more common in individuals diagnosed with depression than in the general population. In a small study, Russ et al.[220] found that four of seven patients suffering from depression had subnormal plasma concentrations of PLP, the active form of vitamin B_6. Likewise, Stewart et al.[221] observed that among a group of 101 depressed outpatients, 21% of those assessed had low plasma levels of pyridoxine.

In a small clinical trial involving 14 institutionalized geriatric patients diagnosed as depressed, Bell et al.[222] reported improved cognitive functioning and depression ratings with coadministration of vitamins B_1, B_2, and B_6 (10 mg each) at the start of tricyclic antidepressant (TCA) therapy using nortriptyline.

Well-designed and adequately powered clinical trials are warranted to further investigate this possible synergy and determine the parameters of its clinical application.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing nortriptyline or related TCA medications are advised to evaluate the patient's nutritional status, especially B vitamins and vitamin D. Nutrient coadministration may be prudent, pending more conclusive evidence from qualified case reports and substantive clinical trials, given the potential for benefit. A low dose of vitamin B_6 (e.g., 10-25 mg/day) may be adequate, especially when used in combination with thiamine and cyanocobalamin (B_1 and B_{12}); other nutrients such as vitamin D warrant significantly higher dose levels (e.g., 800-2000 IU/day). No available research suggests significant risk of adverse effects or interference with the therapeutic efficacy of TCA therapy with recommended doses.

Health care providers are advised to educate patients about the therapeutic benefits of a balanced healthy diet, supportive social engagement, regular exercise, and exposure to sunlight and fresh air and strongly encourage such building of these synergistic lifestyle practices.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Amphetamines, Mixed

Amphetamine aspartate monohydrate, amphetamine sulfate, dextroamphetamine saccharate, dextroamphetamine sulfate; D-amphetamine, Dexedrine.

Methylphenidate (Metadate, Methylin, Ritalin, Ritalin-SR; Concerta).

Combination drug: Mixed amphetamines: Amphetamine and dextroamphetamine (Adderall; dexamphetamine).

Compulsive behavior and anxiety develop in some patients treated with amphetamines, even after the medication is discontinued. Frye and Arnold[223] described the case of an 8-year-old boy in whom anxiety and persistent dextroamphetamine-induced compulsive rituals declined significantly within 3 weeks after initiation of pyridoxine (200 mg) daily for 1 week, followed by by a reduced dose of 100 mg daily. The positive response manifested after a few months of concomitant treatment, with elimination of the drug-induced adverse effects.

Bhagavan and Brin[193] studied serotonin and pyridoxal phosphate (PLP) levels in the blood of 11 hyperactive children and 11 controls and noted significantly lower levels of serotonin in the hyperactive patients than in controls. They found no differences in PLP content of blood between the two groups.

However, when four children who had displayed low serotonin levels were administered oral doses of pyridoxine, these investigators observed an appreciable increase in the serotonin content and a very large increase in the PLP content of blood in the hyperactive patients. These preliminary and indirect research findings suggest that pyridoxine intake, especially relative to tryptophan intake, can alter serotonin levels. However, the clinical significance of these data to vitamin B_6 supplementation in human patients being treated with mixed amphetamines has yet to be thoroughly and systematically researched.

Clinical trials investigating coadministration of pyridoxine/B vitamins along with stimulant medications prescribed for attention-deficit disorder (ADD) may be warranted.

Beta-Adrenoreceptor Antagonists and Calcium Channel Blockers

Beta-1-adrenoreceptor antagonists (beta-1 blocking agents)

Oral forms (systemic)

Evidence: Bisoprolol (Zebeta), metoprolol (Lopressor, Toprol XL).

Extrapolated, based on similar properties: Acebutolol (Sectral), atenolol (Tenormin); combination drugs: atenolol and chlortalidone (Co-Tendione, Tenoretic); atenolol and nifedipine (Beta-Adalat, Tenif), betaxolol (Kerlone); carteolol (Cartrol), esmolol (Brevibloc), labetalol (Normodyne, Trandate); metoprolol combination drug: metoprolol and hydrochlorothiazide (Lopressor HCT); nadolol (Corgard), nebivolol (Nebilet), oxprenolol (Trasicor), penbutolol (Levatol), pindolol (Visken), propranolol (Betachron, Inderal LA, Innopran XL, Inderal); combination drug: propranolol and bendrofluazide (Inderex); sotalol (Betapace, Betapace AF, Sorine), timolol (Blocadren).

Calcium channel blockers

Amlodipine (Norvasc); combination drug: amlodipine and benazepril (Lotrel); bepridil (Bapadin, Vascor), diltiazem (Cardizem, Cardizem CD, Cardizem SR, Cartia XT, Dilacor XR, Diltia XT, Tiamate, Tiazac), felodipine (Plendil); combination drugs: felodipine and enalapril (Lexxel); felodipine and ramipril (Triapin); gallopamil (D600), isradipine (DynaCirc, DynaCirc CR), lercanidipine (Zanidip), nicardipine (Cardene, Cardene I.V., Cardene SR), nifedipine (Adalat, Adalat CC, Nifedical XL, Procardia, Procardia XL); combination drug: nifedipine and atenolol (Beta-Adalat, Tenif); nimodipine (Nimotop), nisoldipine (Sular), nitrendipine (Cardif, Nitrepin), verapamil (Calan, Calan SR, Covera-HS, Isoptin, Isoptin SR, Verelan, Verelan PM); combination drug: verapamil and trandolapril (Tarka).

Evidence of direct pharmacological interactions between vitamin B_6 and either calcium channel blockers or beta blockers is lacking, but there is a broader strategic interaction in terms of cardiovascular risk factors and comprehensive therapeutic strategies related to pyridoxine's role in homocysteine (Hcy) metabolism.

The biochemical conversion of homocysteine to cysteine depends on two consecutive, vitamin B_6–dependent reactions. Homocysteine is strongly associated with atherosclerosis, coronary artery disease, thromboembolism, and vascular endothelial cell injury. There is strong evidence that the prothrombotic and endothelial vascular dysfunction produced by Hcy may result from oxidative stress and subsequent endothelial cell damage. Furthermore, inflammation causes tissue-specific depletion of vitamin B_6. The pathogenic effects of Hcy, inflammation, and cholesterol are additive. Hyperhomocysteinemia is associated with numerous conditions, including coronary disease, stroke, peripheral vascular disease (carotid artery and cerebrovascular atherosclerosis), venous thrombosis, renal disease, diabetes mellitus, and organ transplant.

Ubbink et al.[224] performed oral methionine load tests on 22 vitamin B_6–deficient asthma patients treated with theophylline (a B_6 antagonist) and 24 age-matched and gender-matched controls with normal vitamin B_6 status. Both groups had normal circulating vitamin B_{12} and folate concentrations. Methionine loading resulted in significantly higher increases in circulating total homocysteine (tHcy) and cystathionine concentrations in B_6-deficient subjects compared with controls. However, 6 weeks of vitamin B_6 administration (20 mg/day) significantly reduced post–methionine load increases in circulating tHcy concentrations in deficient subjects, but had no significant effect on the increase in tHcy concentrations in controls. These investigators concluded that a vitamin B_6 deficiency may contribute to metabolic changes associated with premature vascular disease.

Physicians prescribing beta blockers or calcium channel blockers are advised to consider a comprehensive cardiovascular care strategy incorporating vitamin B_6 along with vitamins B_2, B_{12}, omega-3 fatty acids (fish oils), magnesium, and coenzyme Q10. Typical therapeutic dosages of B_6 are in the range of 50 to 200 mg per day, with higher dosages warranting monitoring due to potential adverse effects associated with higher dosages for an extended period.

Corticosteroids, Oral

Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol) prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).

Similar properties but evidence indicating no or reduced interaction effects: Inhaled or topical corticosteroids.

Many review articles suggest that prednisone and related oral corticosteroid drugs can contribute to depletion of vitamin B_6. However, in a double-blind, placebo-controlled trial, Sur et al.[207] found that concomitant therapy with inhaled steroids and pyridoxine (300 mg/day) produced no significant differences (vs. placebo in place of pyridoxine) in the treatment of 31 patients with steroid-dependent asthma for 9 weeks.

Physicians prescribing oral corticosteroids for longer than 2 weeks are advised to evaluate the potential need to coadminister vitamin B_6 to counter the depleting effects of the medication. The limited available evidence suggests that coadministration of vitamin B_6 at low dose levels (e.g., 25-50 mg/day) may be sufficient to prevent drug-induced deficiency, and that larger doses may not provide any additional benefit. However, patients also being treated with theophylline may have greater vitamin B_6 requirement because that agent acts as a B_6 antagonist.

Diclofenac, Ketorolac, and Related Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Diclofenac potassium (Cataflam), diclofenac sodium (Voltaren).

Using a rat model, Rocha-Gonzalez et al.[225] investigated a possible synergistic interaction between oral diclofenac and B vitamins (100:100:1 of vitamin B_1, B_6, and B_{12}, respectively) in increasing the analgesic effect of diclofenac and reducing inflammatory pain. "Diclofenac (0.31-316 mg/Kg), B-vitamins (32-178 mg/Kg), or a combination of B-vitamins and diclofenac was administered orally and the antinociceptive effect was determined" in the rat formalin test. During second

phase of the test, they found that diclofenac, B vitamins, and "fixed-ratio B-vitamins–diclofenac combinations dose-dependently reduced flinching behavior." These researchers concluded that their findings "indicate that oral diclofenac and B-vitamins can interact synergistically to reduce inflammatory pain in the formalin test and suggest the use of those combinations to relief this kind of pain in humans."[225]

Medina-Santillan et al.[226] reported that B vitamins can increase the analgesic effect of ketorolac in the formalin test in the rat. "Ketorolac (0.32-10 mg/Kg, po), B-vitamins (56-316 mg/Kg), or a combination of B-vitamins (either 100:100:1 or 100:100:5 proportion of vitamin B_1, B_6 and B_{12}, respectively) and ketorolac was administered orally and the antinociceptive effect was determined." During second phase of the test, they found that ketorolac, B vitamins, and "fixed-ratio B-vitamins–ketorolac combinations dose-dependently reduced flinching behavior." These researchers concluded that their findings "indicate that oral ketorolac and B-vitamins can interact synergistically to reduce inflammatory pain in the formalin test and suggest the use of those combinations to relief this kind of pain in humans."[226]

These preliminary findings suggest that further research appears warranted, particularly given other emerging data elucidating the relationship between inflammation and depletion of vitamin B_6.[148,149]

Erythromycin and Related Macrolide Antibiotics (Oral)

Erythromycin oral (EES, EryPed, Ery-Tab, PCE Dispertab, Pediazole), troleandomycin (Tao).
Extrapolated, based on similar properties: Azithromycin (Zithromax), clarithromycin (Biaxin), dirithromycin (Dynabac).
Related but evidence against extrapolation: Erythromycin topical (A/T/S, Akne-Mycin, Erygel, Erycette, Eryderm, Erygel).

Oral erythromycin therapy, especially with long-term administration, may interfere with the absorption and activity of vitamin B_6, and other B vitamins, as well as minerals such as calcium and magnesium. Simple preventive action through coadministration of a multivitamin-mineral formulation is prudent when antibiotics are used for more than 2 weeks or repeatedly. Evidence is lacking, and claims of drug impairment are absent, regarding potential pharmacokinetic interference that might occur if these agents were ingested simultaneously; separation of oral intake by at least 2 hours would be judicious, pending substantive research findings.

Broad-spectrum antimicrobial agents tend to damage the ecology of the gastrointestinal tract by eliminating probiotic flora. Synthesis of B vitamins is among the many important functions performed by intestinal microbiota, and their restoration through oral intake of probiotic flora is recommended after use of any significant course of antibiotic medications. Nevertheless, the evidence pertaining to the effects of macrolide antibiotics specifically on vitamin B_6 is suggestive but remains preliminary or inconclusive. The burgeoning body of research underway into the critical role of gut microflora in the normal functioning of the digestive tract, immune system, neurotransmitter synthesis, and other central physiological processes portends a significantly greater knowledge and deeper understanding of this fundamental symbiotic relationship.

Fenofibrate, Bezafibrate, and Related Fibrates

Bezafibrate (Bezalip), ciprofibrate (Modalim), clofibrate (Atromid-S), gemfibrozil (Apo-Gemfibrozil, Lopid, Novo-Gemfibrozil), fenofibrate (Lofibra, Tricor, Triglide).

See also Folic Acid monograph.

Fenofibrate and other fibrates can greatly increase plasma homocysteine levels. Vitamin B_6, along with folic acid, B_{12}, and riboflavin, plays a key role in Hcy metabolism and increasing nutrient intake can lower plasma Hcy concentration. However, circulating levels of these vitamins are not typically lower with fibrates. Although the benefits of folic acid coadministration have been investigated and confirmed, evidence from human research focusing on the interaction between fibrates and vitamin B_6 is lacking. Clinical trials investigating the potential benefits of pyridoxine coadministration during fibrate therapy is warranted. Pending conclusive findings, physicians prescribing fibrates are advised to consider coadministration of vitamins B_6, B_{12}, riboflavin, and folic acid as prudent. In addition to regular exercise and prudent dietary habits, enhanced intake of magnesium, omega-3 fatty acids, L-carnitine, pantethine, and fiber, as well as coenzyme Q10 therapy, may also be beneficial in these cases.

Hormone Replacement Therapy (HRT): Estrogen-Containing and Synthetic Estrogen and Progesterone Analog Medications

HRT, estrogens: Chlorotrianisene (Tace); conjugated equine estrogens (Premarin); conjugated synthetic estrogens (Cenestin); dienestrol (Ortho Dienestrol); esterified estrogens (Estratab, Menest, Neo-Estrone); estradiol, topical/transdermal/ring (Alora Transdermal, Climara Transdermal, Estrace, Estradot, Estring FemPatch, Vivelle-Dot, Vivelle Transdermal); estradiol cypionate (Dep-Gynogen, Depo-Estradiol, Depogen, Dura-Estrin, Estra-D, Estro-Cyp, Estroject-LA, Estronol-LA); estradiol hemihydrate (Estreva, Vagifem); estradiol valerate (Delestrogen, Estra-L 40, Gynogen L.A. 20, Progynova, Valergen 20); estrone (Aquest, Estragyn 5, Estro-A, Estrone '5', Kestrone-5); estropipate (Ogen, Ortho-Est); ethinyl estradiol (Estinyl, Gynodiol, Lynoral).
HRT, estrogen/progestin combinations: Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); conjugated equine estrogens and norgestrel (Prempak-C); estradiol and dydrogesterone (Femoston); estradiol and norethindrone, patch (CombiPatch); estradiol and norethindrone/norethisterone, oral (Activella, Climagest, Climesse, FemHRT, Trisequens); estradiol valerate and cyproterone acetate (Climens); estradiol valerate and norgestrel (Progyluton); estradiol and norgestimate (Ortho-Prefest).
HRT, estrogen/testosterone combinations: Esterified estrogens and methyltestosterone (Estratest, Estratest HS).
See also Oral Contraceptives.

The potential adverse effects of exogenous estrogen (with or without progestins) on the levels and functions of vitamin B_6 remain an area of controversy and discovery. Research into the interactions between OCs and vitamin B_6 has demonstrated an adverse effect on B_6-dependent enzymes along the tryptophan-niacin pathway and revealed the breadth, complexity, and nuances of these issues, particularly with regard to hormone formulations and interindividual variability in drug response.

Conjugated estrogens may be associated with compromised vitamin B_6 status or deficiency. In a small, preliminary trial, Haspels et al.[227] observed a "relative pyridoxine deficiency ... in all of 12 women using conjugated estrogens unopposed by progestagens." They attributed this effect to "disturbed tryptophan metabolism, expressed in increased xanthurenic acid (XA) excretion (greater than or equal to 60 μmol/8 h) during 8 h following oral administration of 2 g L-tryptophan." This finding parallels the results from a number of studies focusing on OCs and potentially extrapolates to such patterns of interaction involving HRT in

postmenopausal women. The authors found that this "disturbance is clear after 1 yr of oestrogen treatment," and that "xanthurenic acid excretion was only slightly increased in 3 women who used progestagens in high dosages at the same time." Based on these findings, the authors suggested that "biochemical changes induced could easily be corrected by administration of vitamin B_6" and concluded by noting that their "cyclic treatment regimen now consists of 25 days of oestrogens per month," after which "a 250 mg tablet per day of vitamin B_6 is prescribed."[227] Further research through well-designed and adequately powered clinical trials is warranted to confirm this adverse interaction, delineate patterns of susceptibility, and develop clinical guidelines for individualized hormone prescription and nutrient coadministration.

Hydroxychloroquine

Hydroxychloroquine (Plaquenil).

In 1991, McCarty[228] reported a case of complete reversal of rheumatoid nodulosis in a woman with a history of seropositive rheumatoid arthritis (RA) of 12 years' duration (with attacks of palindromic rheumatism for 3 years) after treatment with D-penicillamine, pyridoxine, and hydroxychloroquine. The author noted that "this is the first instance of complete resolution of all nodules in a patient with RA with the nodulosis variant." The specific role of vitamin B_6 in this clinical response remains uncertain, as does its generalizability to other patients with RA or similar autoimmune conditions. Further research through well-designed clinical trials may be appropriate.

Ketorolac

Ketorolac (Toradol).

See Diclofenac, Ketorolac, and Related Nonsteroidal Anti-Inflammatory Drugs (NSAIDs).

Nitrofurantoin

Nitrofurantoin (Furadantin, Macrobid, Macrodantin).

Lacerna and Chien[229] described the case of an elderly female patient who developed paresthesias after concomitant intake of nitrofurantoin and vitamin B_6 for an extended period. Corroborative evidence of such an interaction is lacking, as is research specifically investigating the mechanisms of action involved and parameters of clinical significance. The concerns previously discussed regarding the potential adverse effect on vitamin B_6 status due to the antimicrobial activity against probiotic flora in the gastrointestinal tract can be reasonably extrapolated to nitrofurantoin. However, specific human research is lacking to confirm this interaction or any potential benefit of supplementing probiotic flora, vitamin B_6, or other relevant nutrients during or after nitrofurantoin therapy.

Risperidone

Risperidone (Risperdal).

Dursun et al.[230] described the case of a 74-year-old woman who developed neuroleptic malignant syndrome while being treated for schizoaffective disorder with risperidone. Administration of "high-dose vitamin E plus vitamin B_6" effectively alleviated this known adverse drug reaction.

Evidence from further qualified case reports and/or research findings from clinical trials is lacking to confirm whether coadministration of vitamin E and vitamin B_6 might help prevent this condition in patients treated with risperidone and, if so, what dose would be appropriate.

Selegiline

Selegiline (deprenyl, L-deprenil, L-deprenyl; Atapryl, Carbex, Eldepryl, Jumex, Movergan, Selpak).

Selegiline is a highly potent and selective, irreversible inhibitor of B-type monoamine oxidase (MAO), a predominantly glial enzyme in the brain.

Several case reports have described individuals exhibiting the characteristic clinical picture of an extrapyramidal movement disorder due to aromatic L-amino acid decarboxylase (AADC) deficiency, which results in in an impaired synthesis of catecholamines and serotonin and manifests as oculogyric crises and vegetative symptoms. Many of these patients have demonstrated significant clinical improvement when treated with a combination of pyridoxine (an AADC cofactor), selegiline, and bromocriptine, especially when treatment is initiated during the first year of life.[231]

Selective Serotonin Reuptake Inhibitor and Serotonin-Norepinephrine Reuptake Inhibitor (SSRI and SSRI/SNRI) Antidepressants

Citalopram (Celexa), duloxetine (Cymbalta), escitalopram (S-citalopram; Lexapro), fluoxetine (Prozac, Sarafem), fluvoxamine (Faurin, Luvox), paroxetine (Aropax, Deroxat, Paxil, Seroxat), sertraline (Zoloft), venlafaxine (Effexor).

The conversion of tryptophan to serotonin (5-hydroxytryptamine) is catalyzed by a PLP-dependent enzyme. Dopamine, norepinephrine, and GABA are other neurotransmitters synthesized using PLP-dependent enzymes.

Vitamin B_6 deficiency may be more common in individuals diagnosed with depression than in the general population. In a small study, Russ et al.[220] found that four of seven patients suffering from depression had subnormal plasma concentrations of PLP, the active form of vitamin B_6. Likewise, Stewart et al.[221] observed that among a group of 101 depressed outpatients, 21% of those assessed had low plasma levels of pyridoxine.

Several animal and human studies have reported an interaction between pyridoxine intake and tryptophan or histidine affecting brain serotonin and histamine metabolism. Using a rat model and applying different levels of pyridoxine, Lee et al.[232] observed that "when dietary tryptophan was fed at the requirement level, excess pyridoxine caused essentially no changes in hypothalamic serotonin and 5HIAA ... [but that with] elevated tryptophan intake, excess pyridoxine significantly increased serotonin and 5HIAA (+32%, +20%) in the hypothalamus." They interpreted these findings to "indicate a clear interaction between substrate and coenzyme precursor which influences brain metabolism of histamine and serotonin." Ten years later (1998), Schaeffer et al.[233] fed seven female rats (vs. one control) "10, 100, 175 or 250x the National Research Council recommended level of pyridoxine HCl (7 mg/kg) for 10 wk and measured serum amino acids, amino acids and neurotransmitters in brain regions and the binding properties of serotonin receptors in the cerebral cortex using a ketanserin binding assay." They found that "excess dietary pyridoxine affected brain and serum concentrations of some amino acids and binding properties of cortical serotonin receptors in a biphasic pattern over the range of concentrations fed in this study." Bhagavan and Brin[193] studied serotonin and pyridoxal phosphate (PLP) levels in the blood of 11 hyperactive children and 11 controls and noted significantly lower levels of serotonin in the hyperactive patients compared with controls. They found no differences in PLP content of blood between the two groups. However, when four children who had displayed low serotonin levels were administered oral doses of pyridoxine, these investigators observed an appreciable increase in the serotonin content and a very large increase in the PLP content of blood in the hyperactive patients. These preliminary and indirect research findings suggest

that pyridoxine intake, especially relative to tryptophan intake, can alter serotonin levels. However, the clinical significance of these data to vitamin B_6 supplementation in human patients being treated with serotonin reuptake inhibitors has yet to be thoroughly and systematically researched.

Physicians treating individuals diagnosed with depression or other conditions using serotonin reuptake inhibitors are advised to assess vitamin B_6 status and consider coadministration of vitamin B_6, or possibly a B-complex formulation. However, close supervision, regular monitoring, and dose titration are warranted given the theoretical potential for excessive serotonin buildup with suppression of reuptake. Patients stabilized on antidepressants should be advised to avoid sudden changes in dose levels of pyridoxine or other B vitamins, including abrupt termination of supplementation. Further research through well-designed and adequately powered clinical trials is recommended to determine the safety and efficacy of such concomitant therapy and, on confirmation, clinical guidelines for synergistic support. Research into the concomitant application of vitamin B_6 and an SSRI for the management of premenstrual syndrome also deserves consideration.

Health care providers are advised to educate patients as to the therapeutic benefits of a balanced healthy diet, supportive social engagement, regular exercise, and exposure to sunlight and fresh air and strongly encourage building these synergistic lifestyle practices.

Sulfamethoxazole, Trimethoprim-Sulfamethoxazole, and Related Sulfonamides Antibiotics

Sodium sulfacetamide (AK-Sulf, Bleph-10, Sodium Sulamyd), sulfamethoxazole (Gantanol), sulfanilamide (AVC), sulfasalazine (Salazosulfapyridine, salicylazosulfapyridine, suphasalazine; Apo-Sulfasalazine, Azulfidine, Azulfidine EN-Tabs, PMS-Sulfasalazine, Salazopyrin, Salazopyrin EN-Tabs, SAS), sulfisoxazole (Gantrisin); combination drug: sulfamethoxazole and trimethoprim (cotrimoxazole, co-trimoxazole, SXT, TMP-SMX, TMP-sulfa; Bactrim, Bactrim DS, Cotrim, Septra, Septra DS, Sulfatrim, Uroplus); triple sulfa (Sultrin Triple Sulfa).

Sulfamethoxazole and other sulfonamides may interfere with the activity of vitamin B_6, as well as that of folic acid and vitamin K. However, the limited data available suggest that the risk of a clinically significance adverse effect on the physiological functions of vitamin B_6 evidence is low in most individuals treated with sulfamethoxazole for 2 weeks or less. Furthermore, evidence is lacking to indicate that this interaction might occur with trimethoprim alone, apart from combination with sulfamethoxazole.

Physicians prescribing sulfamethoxazole or trimethoprim-sulfamethoxazole for longer than 2 weeks are advised to consider coadministration of vitamin B_6 and other nutrients that may be depleted. Monitoring of nutrient levels may be warranted, especially in individuals with compromised nutritional intake or immune status. Patients may generally benefit from systematic intake of probiotic bacterial flora for several weeks to months after any substantial antibiotic therapy, because 6 months of supplementation with at least 10 billion organisms daily is considered necessary to ensure full restoration of the symbiotic gut flora.

NUTRIENT-NUTRIENT INTERACTIONS

Coenzyme Q10

Coenzyme Q10; CoQ10

Coenzyme Q10 and vitamin B_6 exhibit a synergistic relationship both physiologically and clinically. "The endogenous biosynthesis of the quinone nucleus of coenzyme Q10 (CoQ10) from tyrosine is dependent on adequate vitamin B_6 nutriture."[234] Blood levels of both nutrients tend to decline with age and are associated with many pathological conditions more prevalent among the elderly population.

Coenzyme Q10 and vitamin B_6 have been widely applied in nutritional therapeutics to support healthy cardiovascular function and for the treatment of cardiovascular disease. However, other researchers have focused on the functions and therapeutics of these nutrients in relation to neurological conditions and immune function, some of which are also associated with elevated homocysteine levels.

Folkers et al.[235] observed that blood levels of both CoQ10 and immunoglobulin G (IgG) increased when CoQ10 and pyridoxine were administered together, and when CoQ10 was administered alone, to three groups of human subjects. Likewise, the blood levels of T4 lymphocytes and the ratio of T4/T8 lymphocytes increased when CoQ10 and pyridoxine were administered together and separately. The authors concluded that "these increases in IgG and T4-lymphocytes with CoQ10 and vitamin B_6 are clinically important for trials on AIDS, other infectious diseases, and on cancer." Willis et al.[234] collected blood samples from 29 patients who were not currently taking either CoQ10 or vitamin B_6 as nutritional supplements. They found that "means for all parameters were within normal ranges," but that a "strong positive correlation was found between CoQ10 and the specific activity of EGOT ... and between CoQ10 and the percent saturation of EGOT with PLP." These authors suggested that it would be "prudent to recommend that patients receiving supplemental CoQ10 be concurrently supplemented with vitamin B_6 to provide for better endogenous synthesis of CoQ10 along with the exogenous CoQ10."

In a preliminary study involving 27 patients with Alzheimer's disease, Imagawa[236] demonstrated considerable effectiveness of mitochondrial activation therapy with CoQ10, iron, and vitamin B_6. Subsequently, in a published letter, Imagawa et al.[237] reported that progression of genetically confirmed familial Alzheimer's disease had been halted for 18 to 24 months in a subset of these patients, two sisters, treated with a daily combination of CoQ10 (60 mg), vitamin B_6 (180 mg), and iron (sodium ferrous citrate, 150 mg). Both patients exhibited improved mental status. The younger sister, 49 years old, who had "had a 1-year history of progressive memory impairment," showed marked improvement, such that her "mental state improved to almost normal after 6 months of therapy." The authors concluded that, in contrast to the rapid progression typical in such familial Alzheimer's disease patients, they "consider that treatment prevented the progression of dementia for 1.5-2 years."[237]

Folic Acid (Folate)

Folic Acid (Folate)

Vitamin B_6 and folate work together in a wide range of physiological processes, including the regulation of homocysteine. Their coadministration, often in conjunction with folic acid and riboflavin, can favorably alter methionine and cysteine metabolism and reduce plasma Hcy levels. In a controlled trial involving healthy individuals, Mansoor et al.[238] found that concomitant administration of folic acid (0.3 mg) and of pyridoxine hydrochloride (120 mg) for 5 weeks produced a greater plasma tHcy response than did either nutrient alone. Furthermore, these authors noted that long-term oral administration of vitamin B_6 alone might reduce concentrations of serum folate. Consequently, it would be prudent to "combine

low to medium divided doses" of folic acid with vitamin B_6 routinely, particularly in individuals with known or significant risk for hyperhomocysteinemia.

Iron

Iron

See final paragraph of previous Coenzyme Q10 section for Imagawa's Alzheimer's disease study.[236,237]

Magnesium

Magnesium

Magnesium Magnesium and vitamin B_6 exhibit an interdependent relationship both physiologically and clinically. Concomitant vitamin B_6 can increase bioavailability of oral magnesium by facilitating active transport across cell membranes and significantly elevate mean plasma and red blood cell (RBC) magnesium levels.[197] Conversely, magnesium deficiency can impair conversion of pyridoxine hydrochloride to PLP; consequently, PLP may be more effective with patients experiencing magnesium (or zinc) deficiency or liver disease. Pyridoxine, magnesium, and zinc are all required for the action of delta-6 desaturase, the initial step in the conversion of essential fatty acids to prostaglandins and related regulatory compounds.[239] Concurrent administration of magnesium may prevent insomnia reportedly associated with high-dose intake of vitamin B_6. These two nutrients have been used in combination with zinc and manganese in the treatment of Osgood-Schlatter disease. Likewise, some clinicians have suggested the combination of vitamin B_6 and magnesium for treating social, communication, and behavioral responses of children and adults with autism; research findings have been mixed and inconclusive.[240]

Vitamin B_2 (Riboflavin)

Vitamin B_2 (Riboflavin)

Vitamin B_6 and riboflavin work together in a wide range of physiological processes, including the regulation of homocysteine. Their coadministration, often in conjunction with folic acid and vitamin B_{12}, can favorably alter methionine and cysteine metabolism and reduce plasma Hcy levels.

Vitamin B_{12}

Vitamin B_{12}

Vitamin B_6 and B_{12} work together in a wide range of physiological processes, including the regulation of homocysteine. Their coadministration, often in conjunction with folic acid and riboflavin, can favorably alter methionine and cysteine metabolism and reduce plasma Hcy levels.

Zinc

Zinc

Zinc is involved in the activation of pyridoxine. Pyridoxal kinase, in particular, requires a zinc-ATP complex as a substrate and a zinc-metallothioneine is necessary for the formation of that zinc-ATP complex.[241] Pyridoxine, zinc, and magnesium are all required for the action of delta-6 desaturase, the initial step in the conversion of essential fatty acids to prostaglandins and related regulatory compounds.[239]

In a rat model, Evans[242] found that vitamin B_6 enhances the absorption of zinc. In contrast, in a study involving 40 lactating women, Moser-Veillon and Reynolds[243] observed that B_6 intake significantly increased plasma total vitamin B_6, plasma pyridoxal phosphate (PLP), and milk total vitamin B_6 but exhibited no effect on plasma, erythrocyte, or milk zinc concentrations. However, zinc deficiency can impair conversion of pyridoxine hydrochloride to PLP; consequently, PLP may be more effective with patients experiencing zinc (or magnesium) deficiency or liver disease.

These two nutrients have been used in combination with magnesium and manganese in the treatment of Osgood-Schlatter disease. Likewise, some clinicians have suggested the combination of vitamin B_6 and zinc for treating mental illness, but such approaches remain controversial and unsupported by substantive evidence from well-designed and adequately powered clinical trials.[244,245]

HERB-NUTRIENT INTERACTIONS

Ginger

Ginger *(Zingiber officinale)*

According to most, but not all, researchers and clinicians, vitamin B_6 and ginger *(Zingiber officinale)* can safely and effectively relieve the severity of nausea and vomiting in early pregnancy in many cases.[76-78,246-249] Their concomitant use is common in clinical practice but has not been the subject of high-quality clinical trials; such research is warranted.

The 251 citations for this monograph, as well as additional reference literature, are located under Vitamin B_6 on the CD at the back of the book.

Vitamin B_{12}

Nutrient Name: Vitamin B_{12}.
Synonyms: Cobalamin, cyanocobalamin.
Chemistry and Forms: Adenosylcobalamin, cobalamin, cyanocobalamin, hydroxocobalamin, hydroxycyanocobalamin, methylcobalamin.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Aminoglycoside antibiotics ≈≈≈/☼	Aminoglycosides decrease B_{12} absorption and biosynthesis, interfere with B_{12} metabolism, and increase elimination; also adversely impact bowel flora. Possible significant adverse effects with extended aminoglycoside administration. Methylcobalamin can reduce drug-induced ototoxicity.	Intramuscular (IM) methylcobalamin or oral B_{12} during extended aminoglycoside therapy.
Anticonvulsant medications ⊕≈≈/☼/≈≈≈	Anticonvulsants may decrease absorption of cobalamin. Anemia common due to drug-induced folic acid and B_{12} deficiency. Significant effect plausible; evidence inconclusive.	Supplement B_{12} during extended anticonvulsant therapy. Monitor cobalamin status.
Antidepressants ⊕⊕	Low B_{12} associated with increased susceptibility to depression. Low B_{12} (and folate) status may result in elevated levels of homocysteine and lead to excitotoxic reactions within the CNS. Healthy B_{12} levels may enhance response to antidepressant therapy through multiple mechanisms, including role in biosynthesis of serotonin and dopamine, and S-Adenosylmethionine (SAMe). Certain antidepressants may deplete and/or antagonize B_{12}. Significant effect probable; evidence preliminary.	Coadminister vitamin B_{12}, with folic acid, both for depression and for synergy with pharmacotherapy. Supervision and monitor as nutrients may elevate medication levels.
Bile acid sequestrants ≈≈≈	Bile acid sequestrants may reduce absorption of many nutrients, including B_{12}. Intrinsic factor (IF)-cyanocobalamin complex appears to be strongly adsorbed by cholestyramine and colestipol, but cyanocobalamin itself may not be adsorbed. Mechanisms plausible but evidence minimal and clinical significance uncertain.	Consider multivitamin-multimineral during extended resin therapy; separate intake. Monitor status of B_{12} and other nutrients (particularly fat-soluble nutrients).
Chloramphenicol ≈≈≈/◈≈≈/☼	Chloramphenicol may reduce B_{12} absorption and can oppose the erythropoietic activity of B_{12} (or iron) in treatment of anemia; bone marrow depression possible. Evidence suggests that B_{12} coadministration (with B_6) may reduce or reverse adverse effects associated with chloramphenicol, including optic neuritis.	Lower-dose chloramphenicol may reduce risk of bone marrow suppression. Supplement B_{12} and/or multivitamin-multimineral during extended chloramphenicol. Monitor B_{12} and iron status. High-dose cyanocobalamin and pyridoxine necessary for reversing severe adverse effects.
Clofibrate ☼/≈≈≈	Clofibrate can impair B_{12} absorption; fenofibrate or other fibrates may also. Fenofibrate and bezafibrate (but not gemfibrozil) can cause hyperhomocysteinemia by binding and activating peroxisome-proliferator activated receptors (PPAR) alpha. Clinical significance unclear. Coadministration of folic acid or a vitamin combination with fenofibrate can reduce Hcy elevation; no evidence indicating interference with drug activity.	Coadministration of B_{12}, folic acid, and/or B_6 is advisable with most fibrates, particularly if Hcy elevated. Consider change to gemfibrozil and support healthy lifestyle practices.
Colchicine ≈≈≈	Colchicine may interfere with B_{12} absorption and interfere with B_{12} metabolism by reducing IF-B_{12} receptors. Colchicine-induced neuropathies may be related to B_{12} depletion or another unknown mechanism. Evidence preliminary and clinical significance uncertain.	Coadminister B_{12} as protective, particularly with higher deficiency risk. Separate intake. IM injection may be required if any indications of neuropathy. Monitor B_{12}; urinary methylmalonic acid may be necessary.
Histamine (H_2) receptor antagonists ≈≈≈	H_2 receptor antagonists (H_2RAs) decrease secretion of gastric acid and pepsin, as well as IF, and thus can impair absorption of dietary cobalamin. Possible clinically significant B_{12} depletion, especially in compromised patients.	Supplement B_{12} during extended H_2RA therapy. Monitor cobalamin status.
Metformin Biguanides ≈≈≈/◈≈≈/☼	Biguanides, especially metformin, reduce B_{12} absorption and lower serum B_{12} and holotranscobalamin by depressing IF secretion and interfering with B_{12}/IF uptake at ileal membrane. Possible decrease of folate and increase Hcy.	Supplement B_{12}, folic acid, and calcium. Monitor folate and cobalamin status.
Methotrexate ≈≈≈/◈≈≈/☼/⊕	Methotrexate interferes with folate metabolism and increases risk of B_{12} deficiency, leading to risk of elevated Hcy. Risk is uncertain but probably significant for nutrient adverse effects. B_{12} is not contraindicated, although prolonged use of therapeutic doses in cancer patients may be problematic, but folic acid is generally contraindicated in cancer treatment (except for folinic acid "rescue" after high-dose methotrexate).	Supplement B_{12}. Coadminister folic acid with rheumatoid arthritis and psoriasis; avoid with cancer. Monitor folate and cobalamin status.
Nitrous oxide (N_2O) ≈≈≈/☼	N_2O inactivates B_{12}, methionine synthase. Chronic N_2O exposure may lead to B_{12} deficiency, decreased folate activity, and possibly elevated Hcy levels. Clinical significance controversial; evidence mixed.	B_{12} supplementation may be prudent with long-term daily exposure. Monitor cobalamin and folate status.
Oral contraceptives (OCs) ≈≈≈/☼	Decreased B_{12} levels associated with OC use. B_{12} supplementation may reduce adverse effects associated with OC use (e.g., elevated Hcy). Clinical significance controversial; evidence strong but mixed.	B_{12} supplementation may be beneficial. Monitor cobalamin, folate, and Hcy.
Pemetrexed ☼/⊕⊕	Pemetrexed inhibits several folate-dependent enzymes and may cause serious adverse effects, including elevated Hcy. Folic acid and B_{12} can reduce Hcy, enhance drug safety profile, and reduce drug toxicity, without reducing efficacy or survival time.	Concomitant B_{12} and folic acid, with supervision. Closely monitor cobalamin, folate, and Hcy.
Proton pump inhibitors (PPIs) ≈≈≈/☼	PPIs decrease secretion of gastric acid and thus can impair absorption of dietary B_{12}. Possible clinically significant B_{12} depletion, especially in compromised patients, CYP2C19 polymorphism, Zollinger-Ellison syndrome, and atrophic gastritis.	Oral or IM cobalamin recommended. Monitor cobalamin and folate status.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Zidovudine/AZT Reverse-transcriptase inhibitor (nucleoside) antiretroviral agents ≈≈≈	Individuals with HIV/AIDS tend to exhibit low levels of vitamin B_{12} and suffer from B_{12} malabsorption. B_{12} deficiency and its sequelae are often aggravated by antiretroviral agents. Both trends are amplified at more advanced stages. However, coadministration of vitamin B_{12} and folinic acid does not appear to prevent or significantly reduce AZT-induced bone marrow suppression.	Regularly monitor nutritional status and blood counts of HIV-infected patients. Consider concomitant B_{12} and folate; increased dose with anemia or granulocytopenia.

NUTRIENT DESCRIPTION

Physiology and Function

Vitamin B_{12} is the generic term for the group of compounds, collectively known as *cobalamins*, that exhibit the biological activity of cyanocobalamin. Vitamin B_{12} was isolated from liver extract in 1948 and was shown to control pernicious anemia; its structure was elucidated in 1955, and cobalamin was first synthesized in 1973. Cobalamin is the precursor to methylcobalamin and adenosylcobalamin, the bioactive cofactor forms of cobalamin. This water-soluble, crystalline substance derives its red color from the heavy metal cobalt molecule it contains. It is susceptible to degradation by dilute acid, alkali, light, and oxidizing or reducing agents; 30% is typically destroyed by cooking.

Vitamin B_{12} from foods is released from the protein complex that it comes from via the action of hydrochloric acid and proteases. The absorption of cobalamin is highly dependent on *intrinsic factor*, a protein produced by the parietal cells, without which less than 1% of vitamin B_{12} would be absorbed. The secreted intrinsic factor binds to the B_{12}, enabling transfer of compound across the intestinal mucosa, and the resulting complex travels down to the ileum, where it is absorbed from the terminal aspect in the presence of calcium. Vitamin B_{12} is normally actively transported into the blood via protein binding to transcobalamin II and carried to the liver, its major storage site for up to 3 years, and to the kidneys and adrenals. It is distributed throughout the body, where it is converted in tissues to active coenzymes, methylcobalamin and deoxyadenosylcobalamin, and plays a vital role in the metabolism of all cells, especially those of the gastrointestinal tract, bone marrow, and nervous tissue. Excretion is through the urine.

Vitamin B_{12} acts as a coenzyme for various metabolic functions, including fat and carbohydrate metabolism and protein synthesis, and is used in cell replication and hematopoiesis. Its key functions include activation of folate to its active form (tetrahydrofolate, THF); conversion of homocysteine to methionine; fat and carbohydrate metabolism; synthesis of DNA and myelin; and antioxidant (maintains reduced glutathione).

Cobalamin is involved as a cofactor in the transfer of methyl groups in the synthesis of methionine and in folic acid metabolism. In particular, it is needed to remove the methyl group from methyltetrahydrofolate (MTHF) so that THF can be used for reducing RNA in the synthesis of DNA. Vitamin B_{12} is necessary for the maturation of red blood cells (RBCs) as well. Thus, in the absence of B_{12}, DNA is severely compromised, and RBCs grow without dividing, becoming megaloblasts, thus the term *megaloblastic anemia*, which occurs with deficiencies of either folate or B_{12}.

Vitamin B_{12} and folic acid work together to regulate homocysteine (Hcy) levels. Methyl-B_{12} is used to transfer the methyl group onto Hcy to form methionine. Methionine is an essential sulfur-containing amino acid that is converted in the liver into *S*-adenosylmethionine (SAMe), considered the activated form of methionine. Methionine is important in methyl transfers and is necessary for the synthesis of myelin sheaths, among numerous other vital functions. Methionine synthase (5-MTHF–homocysteine S–methyltransferase) catalyzes the cobalamin-dependent methylation of Hcy, using 5-MTHF as the methyl donor. Defects in methionine synthase result in hyperhomocysteinemia and are implicated as the lesion in the cblG complementation group of disorders in cobalamin metabolism. Lower Hcy levels are associated with decreased risk of cardiovascular disease; high Hcy levels may also be associated with Alzheimer's disease, osteoporosis, and strokes. Methionine synthase reductase (MSR) is responsible for the reductive methylation and reactivation of methionine synthase with SAMe as a methyl donor. MSR is a member of the ferredoxin-NADP reductase family of electron transferases, containing the FMN, FAD, and NADPH binding sites necessary to maintain methionine synthase in its functional state.[1] SAMe plays an important role in detoxification processes, the synthesis of antioxidants, and the regulation of emotional states.

Vitamin B_{12} is also involved in carbohydrate metabolism, plays a key role in nerve cell activity, and is required for the synthesis of myelin. Lactic acid and pyruvate production can increase from 50% to 100% during B_{12} deficiency. Neurological problems often occur when there is a B_{12} deficiency because the nervous system relies on carbohydrates as its main source of fuel.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Vitamin B_{12} deficiency is a common but underrecognized, yet easily treatable disorder in older adults. Although several causes exist, food-cobalamin malabsorption is considered the most common etiology. Therapeutic administration of vitamin B_{12} is used primarily to prevent or treat a deficiency state or counter depletion. Although oral intake can serve some supportive function, intramuscular injection was considered the primary therapeutic mode of administration for many years. More recently, it has been shown that large oral doses (1-2 mg/day) are equally effective in treating even the severe B_{12} deficiency associated with pernicious anemia. Concomitant folic acid therapy is also necessary in many circumstances.

Possible Uses

Acquired immunodeficiency syndrome and human immunodeficiency virus (AIDS/HIV) support, age-related cognitive decline (with vitamin B_{12} deficiency), age-related hearing dysfunction, allergies, Alzheimer's disease, anemia (for thalassemia if deficient), anemia (if deficient), anemia of pregnancy, asthma, atherosclerosis, atopic dermatitis, Bell's palsy, bipolar disorder, bursitis, canker sores (for deficiency only), cardiac events and death (risk reduction after first stroke), chronic

fatigue syndrome, contact dermatitis, Crohn's disease, cyanide poisoning (hydroxycobalamin form only), cystic fibrosis (with vitamin B_{12} deficiency), depression (with vitamin B_{12} deficiency), dermatitis herpetiformis (with vitamin B_{12} deficiency), diabetes mellitus, diabetic neuropathies, diabetic retinopathy, Down's syndrome, heart attack, hepatitis, herpes zoster, hives, hypercholesterolemia, hyperhomocysteinemia, immune function, inherited cobalamin disorders, insomnia, low back pain, lung cancer (risk reduction), male infertility, methionine synthase reductase (MSR) deficiency (genetic), methionine synthase apoenzyme deficiency (genetic), methylmalonic aciduria (genetic), multiple sclerosis, neural tube defects (risk reduction), neuralgias, neuropathy, osteoporosis (with hyperhomocysteinemia), pain, pernicious anemia, phenylketonuria (with vitamin B_{12} deficiency), presurgery and postsurgery support, postherpetic neuralgia, preclampsia, pregnancy support, restless leg syndrome, retinopathy (associated with childhood diabetes), schizophrenia, sciatica, seasonal affective disorder, seborrheic dermatitis, sickle cell anemia (with B_{12} deficiency), stroke and second stroke (risk reduction), thyrotoxicosis, tinnitus, vitamin B_{12} deficiency, vitiligo.

Deficiency Symptoms

Increased risk of vitamin B_{12} deficiency is associated with deficiency of intrinsic factor and pernicious anemia; achlorhydria; atrophic gastritis; gastric carcinoma; gastrectomy, especially of the cardia or fundus; pregnancy and lactation; malnourished children; the elderly, especially those physically disabled and with urinary incontinence, tinnitus, or hearing loss; HIV-infected individuals; psychiatric disorders; liver disease or cancer; *Helicobacter pylori* infection; intestinal diseases, especially involving malabsorption, such as celiac disease, Crohn's disease, colitis, chronic diarrhea (e.g., in AIDS), pancreatic disease, and tapeworms; vegan diets, especially over an extended period; chronic heavy cigarette smoking and/or alcohol use; excessive or prolonged use of medications such as antibiotics, anticonvulsants, cholestyramine, colchicine, gentamicin, metformin, neomycin, and para-aminosalicylic acid (PAS); protracted intake of megadoses of vitamin C and copper.

Genetic

Deficiency of methylmalonyl-CoA mutase, leading to methylsmalonic aciduria.

Elevated adenosylcobalamin, most likely due to a perturbation in cofactor binding.

Defects in methionine synthase result in hyperhomocysteinemia and are implicated as the lesion in the cblG complementation group of disorders in cobalamin metabolism.

Genetic mutations in the cobalamin-binding domain of methyltransferase.

Methionine synthase reductase (MSR) deficiency, such as mutation(s) in cblE complementation group.

Signs and Symptoms of B_{12} Deficiency

Depression, irritability, agitation, bone loss, confusion and memory loss (especially in elderly), fatigue, psychosis, classic pernicious anemia due to lack of intrinsic factor, macrocytic anemia, decreased phagocyte and polymorphonucleocyte response, impaired lymphocyte response, poor blood clotting and easy bruising, progressive peripheral neuropathy, spinal degeneration, unstable gait, decreased coordination, paresthesias, loss of appetite, nausea, vomiting, glossitis, tongue and mouth irregularities, achlorhydria, dermatitis and skin sensitivity.

Complications associated with long-term depletion of this nutrient can take years to develop, and frank vitamin B_{12} deficiency is considered rare. Years of deficiency are usually required before hematological and neurological signs and symptoms become evident. Vitamin B_{12} deficiencies manifest primarily as anemia and neurological changes. Pernicious anemia is usually the first symptom of B_{12} deficiency and results from either inadequate intake or inhibited absorption associated with reduced gastric secretion of intrinsic factor. Vitamin B_{12} deficiency, and subsequent impairment of cell replication in atrophy and inflammation of mucus membranes in the mouth and throughout the digestive tract, not only results in reduced absorption of nutrients, gastric atrophy, anorexia, and weight loss, but also creates a gastric environment of increased susceptibility to imbalance and infection. Thus, numerous studies have observed a strong association between *Helicobacter pylori* and B_{12} deficiency, even in the absence of gastric atrophy,[2,11] with infection detected in 56% of individuals diagnosed with pernicious anemia in one trial.[12] Likewise, inhibited DNA synthesis associated with B_{12} deficiency can lead to megaloblastic anemia and manifest as weakness, decreased ability to concentrate, and shortness of breath. Cobalamin-deficiency polyneuropathy is considered particularly difficult to diagnose, and deficiency for longer than 3 months can result in irreversible degenerative central nervous system (CNS) lesions. Low B_{12} levels may also be associated with an increased risk of brain disorders, birth defects, colon cancer, and heart disease. Vitamin B_{12} deficiency can mask signs of polycythemia vera.

In a clinical trial, Eussen et al.[13] found that the lowest dose of oral cyanocobalamin required to normalize mild vitamin B_{12} deficiency is more than 200 times greater than the recommended dietary allowance (RDA).

Dietary Sources

Liver, meat, salt-water fish, oysters, milk, eggs, aged cheese such as Roquefort, fortified brewer's yeast. All foods of animal origin, especially organ meats, provide vitamin B_{12} because it is produced by microbial synthesis in the digestive tract of animals. It does not occur in fruits, vegetables, grain, or legumes. A few foods of vegetable origin, specifically seaweed and microalgae (including nori, chlorella, and spirulina) and tempeh, can provide small but inconsistent amounts.[14,15]

Nutrient Preparations Available

Hydroxycobalamin and cyanocobalamin are synthetic forms of vitamin B_{12}. Methylcobalamin and 5-deoxyadenosylcobalamin are the two forms of vitamin B_{12} that occur naturally in foods.

Hydroxycobalamin, cyanocobalamin, and adenosylcobalamin are the principal forms used in conventional clinical practice. Methylcobalamin is also used but is very expensive.

Absorption of large doses of B_{12} in the form of oral supplements is relatively poor. Sublingual forms are available but may not offer significant absorption advantages. Intramuscular or deep subcutaneous injection, usually as hydroxycobalamin, is the most effective route of B_{12} administration, especially for the elderly or those suffering from chronic depletion. However, some research indicates that oral doses may be as effective, even in the elderly.[13] Large doses (e.g., 1 mg),

whether sublingual or oral, completely overcome the need for intrinsic factor.

Dosage Forms Available

Capsules, effervescent tablets, gels, injectable (prescription only), intranasal sprays, liposomal sprays, liquids, lozenges, powder, sublingual lozenges, tablets.

Dosage Range

Adult

Dietary: 1 to 3 µg daily.

Supplemental/Maintenance: 100 µg daily. Vegans (individuals who avoid all foods of animal origin) will generally benefit from a daily dose of 2 to 3 µg or more of vitamin B_{12}. Individuals who include animal products in their regular diet usually do not need to supplement with B_{12}. However, several studies show that B_{12} absorption declines with increasing age and suggest that the elderly may generally benefit from regular supplementation with 10 to 25 µg per day of vitamin B_{12}.[16-19]

Pharmacological/Therapeutic: Pharmacological dosages in the scientific literature range from 100 to 3000 µg. For example, long-term supplementation might involve 30 µg/day for 5 to 10 days initially, followed by 100 to 200 µg per month. A daily dose of 250 µg is often used to treat deficiency, and daily doses as high as 2000 µg have been used in chronic renal insufficiency. Therapy for pernicious anemia usually involves vitamin B_{12} injections, but oral administration of 1000 µg/day may be effective for some individuals.[20-25] Some evidence indicates that individuals, particularly elderly, whose serum cobalamin concentration is less than 300 pg/mL should receive replacement parenteral therapy. Nonspecific neurological signs and symptoms, particularly in the elderly, including fatigue, appear to respond to B_{12} supplementation, despite low-normal serum levels. Ralph Carmel, a hematologist, has researched and published extensively on this issue.

Gel, intranasal (Nascobal): 500 µg/0.1 mL (5 mL)

Injection: 100 µg/mL (1 mL, 10 mL, 30 mL); 1000 µg/mL (1 mL, 10 mL, 30 mL)

Tablet [OTC]: 50 µg, 100 µg, 250 µg, 500 µg, 1000 µg.

Dibencozide is a supplemental form of deoxyadenosylcobalamine that has been widely used by athletes and bodybuilders. Toxic: Few adverse effects and no reports of toxicity have been associated with B_{12} therapy, even at unusually high oral doses such as 5000 µg/day.

Pediatric (<18 years)

Dietary:

Infants, birth to 6 months: 0.4 µg/day (AI, adequate intake)

Infants, 7 to 12 months: 0.5 µg/day (AI)

Children, 1 to 3 years: 0.9 µg/day (RDA)

Children, 4 to 8 years: 1.2 µg/day (RDA)

Children, 9 to 13 years: 1.8 µg/day (RDA)

Adolescents, 14 to 18 years: 2.4 µg/day (RDA)

Pharmacologic/Therapeutic: 1 to 5 mg given in single doses of 100 µg over 2 or more weeks, followed by 30 to 50 µg per month.

Laboratory Values

Elevated levels of urinary methylmalonic acid (MMA) is the most reliable sign of a need for increased intake of B_{12}, regardless of the serum level of the vitamin.

Serum Vitamin B_{12}

Normal range: 150 to 750 pg/mL; this represents 0.1% of total body content.

Levels less than 150 pmol/L indicate clear deficiency.

Serum levels may be normal even when anemia or neurological symptoms due to vitamin B_{12} deficiency are present.

Urinary Methylmalonic Acid

Levels greater than 5 µg/mg creatinine indicate deficiency.

Urinary MMA is a more sensitive index of B_{12} status than serum levels of the vitamin.

Hypersegmentation Index of Nuclei of Neutrophils

The ratio of neutrophils with five lobes or more to those with four lobes or less; values greater than 30% indicate deficiency.

Note: These findings can also result from folate deficiency and are not reliable during pregnancy.

Note: Antibiotics may interfere with microbiological assay for serum and erythrocyte vitamin B_{12} (false low results).

Methotrexate, pyrimethamine, and most antibiotics invalidate folic acid and vitamin B_{12} diagnostic microbiological blood assays.

SAFETY PROFILE

Overview

Vitamin B_{12} is nontoxic in recommended dosages.

Nutrient Adverse Effects

No toxicities have been reported or suspected as being associated with vitamin B_{12} in healthy adults, even at very high oral doses (>10 mg/day). However, no studies have specifically confirmed long-term safety in individuals with severe hepatic or renal disease.

General Adverse Effects

Adults: Infrequent diarrhea, urticaria, itching skin, peripheral vascular thrombosis. Megadoses of B_{12} may cause or exacerbate acne symptoms.[26-28]

Hydroxycobalamin is usually administered as an injectable. Some evidence indicates that the cyano part of cobalamin may be toxic to cells (related to cyanide) and rarely may provoke significant or even severe reactions.[29,30] Most, but not all, injectable vitamin B_{12} products contain preservatives; some may contain benzoyl alcohol. An intradermal test dose should be performed for hypersensitivity. Avoid use of preparations containing benzoyl alcohol in premature infants.

Reactions to intramuscular injections of cyanocobalamin:

Less than 10%: Weakness (1%-4%), anxiety, pain, nervousness, hypoesthesia, dizziness, paresthesia, abnormal gait, headache (2%-11%), sore throat, dyspnea, rhinitis, nausea and vomiting, dyspepsia, diarrhea, back pain, arthritis, myalgia, urticaria.

Less than 1%: Peripheral vascular thrombosis, urticaria, anaphylaxis, congestive heart failure (CHF), pulmonary edema.

Adverse Effects Among Specific Populations

Studies specifically confirming long-term safety in individuals with severe hepatic or renal disease are lacking.

Pregnancy and Nursing

No significant safety issues have been demonstrated regarding the use of vitamin B_{12} by pregnant or lactating women. B_{12} enters breast milk; compatible.

Infants and Children

No significant safety issues have been demonstrated regarding the use of vitamin B_{12} by infants or children. Supplementation can be important for children on a vegetarian, especially vegan, diet.

Contraindications

Hypersensitivity to cyanocobalamin or any component of the formulation, cobalt; patients with hereditary optic neuropathy (Leber's disease).

Precautions and Warnings

Apparent vitamin B_{12} deficiency should not be treated with vitamin B_{12} alone until a definitive diagnosis has been established; that is, folate deficiency has been ruled out.

Treatment of vitamin B_{12}–related megaloblastic anemia may result in severe hypokalemia, sometimes fatal, when anemia corrects, due to cellular potassium requirements. Because of the rapid DNA synthesis, with resulting rapid cell division in bone marrow, when a severe B_{12} deficiency is corrected, it is prudent to supplement folate (1 mg/day) and ensure high dietary/supplemental (prescription) potassium intake. Conversely, because of vitamin B_{12}'s role in DNA synthesis, high doses of B_{12} and folic acid should generally be avoided in oncology patients with known tumors.

INTERACTIONS REVIEW

Strategic Considerations

Vitamin B_{12} deficiency inhibits DNA synthesis, which systemically affects the growth, function and repair of all cells and tissues. Other than the expected epidemiological patterns among individuals exclusively under a long-term vegan diet, the elderly, malnourished, heavily medicated, and institutionalized populations are particularly at risk for developing deficiency or subclinical depletion patterns. Healthy gastric pH and gut ecology play a critical role in B_{12} absorption and metabolism. Some reviewers have explored whether the association between *Helicobacter pylori* infection and coronary heart disease might be related to reduced cobalamin absorption and cobalamin status and, consequently, elevated homocysteine levels, but no conclusions have been ventured.[9] Scientific knowledge of the diverse roles and profound implications of enteric flora and healthy gut ecology has begun to emerge and is contributing to a fundamental reconceptualization of our understanding of assimilation and nutriture, immune function, neurotransmitter metabolism, and other core aspects of human physiology.[31-35]

The primary commonly accepted drugs that deplete vitamin B_{12} include AZT, cholestyramine, colchicine, and metformin. Histamine (H_2) blockers and proton pump inhibitors impair B_{12} absorption from food but do not appear to interfere significantly with B_{12} absorption from supplemental sources. Medications that reduce folate absorption or interfere with its metabolism, such as methotrexate, oral contraceptives, and anticonvulsants, also contribute to B_{12} depletion and decreased function. Generally, avoiding high doses of B_{12} and folate with oncology patients is prudent, pending careful clinical study of the issue, because of vitamin B_{12}'s role in DNA synthesis and because large doses of B_{12}/folate might stimulate tumor growth.

Vitamin B_{12} deficiency is more common than suspected and can be difficult to recognize because of its often subtle and pervasive symptomatology at early and middle stages. Serum levels may be normal even when significant deficiency has been present for an extended period; urinary MMA provides a more sensitive assessment of B_{12} status. There is some evidence that supplementation can improve symptoms of diabetic neuropathy and delay the progress of dementia related to vitamin B_{12} deficiency. Health care providers are advised to elicit risk factors and discuss susceptibility, consequences, and preventive steps with patients at risk for B_{12} deficiency or depletion. Hydroxycobalamin and adenosylcobalamin are the preferred forms of injectable B_{12}; bioactive methylcobalamin tablets are the preferred sublingual form.

It appears that generous quantities of B_{12} may be critical to effectiveness much more often than previously thought, especially in the elderly. Generally, nutritional education has framed B_{12} dosing in single-digit micrograms, and folate dosing in hundreds of micrograms, because of the difference in quantity that prevent serious deficiency states. However, a pivotal clinical trial by Eussen et al.[13] showed that once deficient (by MMA levels), it takes 500 to 600 µg of oral vitamin B_{12}, at minimum, to correct an established pattern of "mild" depletion. Moreover, it is advisable always to give equivalent amounts of B_{12} with folate. The primary caution generally voiced against folic acid administration is the oft-repeated warning that vitamin B_{12} deficiency, especially severe deficiencies such as those associated with pernicious anemia, might be masked. This caution, however, seems misplaced or at least uninformed, since almost all folic acid products on the market are formulated with vitamin B_{12}, at the least, or a comprehensive range of synergistic nutrients, as in a multivitamin or B-complex formulation. All health care providers trained and experienced in nutritional therapeutics would routinely coadminister folic acid and vitamin B_{12} as a matter of safety, synergy, and efficacy.

Homocysteine (Hcy) regulation appears as a recurrent theme in reviewing the strategic significance of drug interactions with dietary sources and supplemental forms of vitamin B_{12}. The pervasive and destructive effects of elevated Hcy levels are well documented and widely known. Methionine synthase, the enzyme that metabolizes Hcy to methionine, uses 5-methyltetrahydrofolate and vitamin B_{12} as cofactors. Folic acid may have antiatherogenic mechanisms independent of lowering Hcy levels. Apart from effects on the vascular system, plasma total homocysteine (tHcy) level (and low serum folate concentrations) is an independent risk factor for dementia, as well as low bone mineral density, particularly among women.[36-42]

The evolving debate as to whether Hcy represents a causal or coincident factor in heart disease, stroke, and related conditions shifted to a new level with publication of the Vitamin Intervention for Stroke Prevention (VISP) trial. When the VISP trial's intention-to-treat analysis failed to show efficacy of combined-vitamin therapy for recurrent vascular events in patients with nondisabling stroke, Spence et al.[43] conducted an "efficacy analysis limited to patients most likely to benefit from the treatment, based on hypotheses arising from evidence developed since VISP was initiated." They cited many reasons for the lack of observed efficacy, including "folate fortification of grain products, inclusion of the recommended daily intake for B_{12} in the low-dose arm, treatment with parenteral B_{12} in patients with low B_{12} levels in both study arms, a dose of B_{12} too low for patients with malabsorption, supplementation with

nonstudy vitamins, and failure of patients with significant renal impairment to respond to vitamin therapy." Consequently, they "excluded patients with low and very high B_{12} levels at baseline (< 250 and > 637 pmol/L, representing the 25th and 95th percentiles), to exclude those likely to have B_{12} malabsorption or to be taking B_{12} supplements outside the study and patients with significant renal impairment." On analyzing data for this subgroup of 2155 patients (37% female, mean age of 66 ± 10.7 years), "there was a 21% reduction in the risk of events in the high-dose group compared with the low-dose group." They also noted that "patients with a baseline B_{12} level at the median or higher randomized to high-dose vitamin had the best overall outcome, and those with B_{12} less than the median assigned to low-dose vitamin had the worst." They concluded: "In the era of folate fortification, B_{12} plays a key role in vitamin therapy for total homocysteine. Higher doses of B_{12}, and other treatments to lower total homocysteine may be needed for some patients."[43]

Subsequently, the NORVIT and HOPE-2 trials supported the conclusions of a consistent body of scientific research demonstrating that these nutrients help lower Hcy levels, but failed to support the hypothesis that lowering Hcy levels alone will provide protection against a future cardiovascular event in high-risk patients with established cardiovascular disease. For example, in the Norwegian study of post–myocardial infarction (MI) patients randomized to a folate/B_{12}/B_6 formulation or placebo, Bønaa et al.[44,45] observed a pattern of increased risk of a second MI in the intervention group, despite a lowering of Hcy. Although relevant to certain patient populations, the findings from these trials suggest that such a study of secondary prevention (patients with previous MI) has limited applicability to primary prevention (individuals without previous vascular events) in healthy individuals and in those with elevated risk. Notably, the HOPE-2 study demonstrated a statistically significant, 25% reduction in nonfatal strokes.[46]

Nevertheless, the current data are confounded because all patients were taking standard post-MI medications, such as beta blockers, angiotensin-converting enzyme (ACE) inhibitors, and aspirin, and investigators did not monitor drug levels to see if the B vitamins were depleted by the medications or, conversely, if the medications were impaired or levels lowered by the nutrients, as is possible if they induce the pregnane X receptor (PXR), as occurs, for example, with vitamin E.[47,48] Such potentially significant variables, which were not assessed or factored in, might explain the unexpected "increased risk" associated with the B vitamins, which would actually be analogous to poor compliance with medication. Research into PXR is in preliminary stages, and a focus on its relevance to B vitamins may be warranted and could shed some light on these and other findings. More broadly, such findings do not detract from other potential benefits derived from lowering Hcy levels, or at least reversing processes associated with elevated Hcy.

The causes of hyperhomocysteinemia are broadly categorized as "inherited" and "acquired"; many involve vitamin B_{12} (and folate) nutriture, metabolism, and function. The inherited causes include MTHFR deficiency or defect, methionine synthase defect, vitamin B_{12} transport defect, vitamin B_{12} coenzyme synthesis defect, and cystathionine beta-synthase deficiency. The acquired cause can be grouped as vitamin deficiencies, chronic diseases, and medication effects. Nutritional deficits of vitamin B_{12}, folic acid, and vitamin B_6 can usually be remedied by ensuring adequate dietary sources and administering supplements providing these synergistic nutrients. As with folate, medications that adversely affect B_{12} status and function constitute one of the primary risk factors for hyperhomocysteinemia. Fortunately, this last factor may be the most amenable to clinician intervention—with this monograph being a tool in providing safe and effective medical management by employing an evidence-based, integrative approach to health care delivery.

NUTRIENT-DRUG INTERACTIONS

Aminoglycoside Antibiotics

Evidence, supportive interaction: Gentamicin (G-mycin, Garamycin, Jenamicin).
Evidence, nutrient depletion: Neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin).
Extrapolated, based on similar properties: Amikacin (Amikin), kanamycin (Kantrex), netilmicin (Netromycin), paromomycin (monomycin; Humatin), streptomycin, tobramycin (AKTob, Nebcin, TOBI, Tobrex).

Interaction Type and Significance
≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Nutrient Depletion Probability: **2. Probable**
Evidence Base: ● **Consensus**

Coadministration Benefit Probability: **2. Probable**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action
Aminoglycosides, particularly neomycin, are typically recognized to decrease absorption, reduce endogenous synthesis, interfere with metabolic functions, and increase elimination of vitamin B_{12} and many other nutrients.[49,50] Eradication of healthy intestinal bacterial flora and disruption of gut ecology by antimicrobials can reduce or eliminate the endogenous synthesis of B_{12} by intestinal microbiota.[51,52]

Ototoxicity, a common adverse effect of medication in this class, can be greatly reduced by simultaneous administration of methylcobalamin. Methylcobalamin's inhibition of the ototoxic effect of gentamicin may derive from the vitamin's inherent nutritive effect on nerve cells. Although recent research indicates that free-radical formation may be pivotal in aminoglycoside-induced ototoxicity, the mechanism of this probable protective interaction remains unclear. Nevertheless, cobalamin plays a fundamental role in the synthesis of methionine and glutathione peroxidase, both of which appear to provide significant antioxidant and neuroprotective activity.

Research
Elevated aminoglycoside blood levels have demonstrated a strong tendency to induce hearing loss and impair equilibrium (eighth cranial nerve disease), often permanently.[53-55] Moore et al.[56] reported that 22% of patients receiving aminoglycosides experienced hearing loss, and the incidence of ototoxicity may be as high as 75% in patients undergoing streptomycin therapy for more than 60 days. Familial susceptibility to aminoglycoside ototoxicity has been discussed in several studies[57-59] and appears to result from the A1555G mutation in the mitochondrial DNA.[60] Oxidative damage appears to be central to the kidney damage often associated

with gentamicin and other aminoglycosides.[61] Furthermore, patients with kidney disease may have increased aminoglycoside blood levels and increased susceptibility to these and other adverse effects. Interestingly, in the physiological model of classical Chinese medicine, the functions of the inner ear are traditionally associated with the kidneys; embryologically, the two tissues originate from the same cells. Aminoglycosides are also known to cause muscular problems, resulting in further muscle weakness in patients with myasthenia gravis, Parkinson's disease, or similar conditions.

Aminoglycosides have been shown to activate and increase the rate of production of oxygen metabolites in the cochlea of mature and developing rats.[62] In vitro experiments indicate that scavengers of such reactive oxygen species, particularly D-methionine, can exert a neuroprotective effect on vestibular sensory cells in relation to gentamicin ototoxicity when combined with either a neurotrophin or a calpain inhibitor.[63] Animal research in aminoglycoside ototoxicity has demonstrated significantly decreased levels of superoxide dismutase, catalase, glutathione peroxidase, glutathione-*S*-transferase, glutathione reductase activities, and malondialdehyde in cochlear samples from albino guinea pigs administered 200 mg/kg/day amikacin for 28 days. This study showed that differences in cochlear antioxidant enzyme activity between treated and control groups inversely correlated significantly with the change in auditory brainstem response thresholds, with the greatest correlation for the high frequencies, which are most affected by aminoglycosides.[64] Subsequently, Jin and Sheng[65] found that simultaneous administration of methylcobalamin greatly reduced the ototoxic effect of gentamicin on the inner ear of guinea pigs.

The potential relevance to vitamin B_{12} nutriture to inner ear lesions is suggested by the findings of Shemesh et al.,[66] who reported a 47% incidence of vitamin B_{12} deficiency in patients with chronic tinnitus and noise-induced hearing loss. The emerging picture of aminoglycoside-induced oxidative stress and observed benefits conferred by cobalamin in reducing the severity of resulting ototoxicity strongly suggest that concomitant administration of vitamin B_{12} may provide more than protection against drug-induced depletion. Further research involving well-designed clinical trials are clearly warranted to investigate the potential of this nutrient in integrative care strategies in those cases where gentamicin, tobramycin, amikacin, and other aminoglycosides are indicated as therapeutically appropriate.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

When used appropriately, aminoglycosides can play a critical role in the treatment of many life-threatening infections. These potent systemic antibacterial and antimycobacterial agents are typically administered in an inpatient setting intravenously, by inhalation, or by irrigation, and their adverse effects are well documented and generally recognized. Short-term use of aminoglycosides, such as administration of oral neomycin in preparation for surgery, is unlikely to lead to clinically significant B_{12} deficiencies, because people with normal B_{12} absorption store at least a 3-year supply in the liver. However, the high safety profile of B_{12} and the lack of evidence indicating that B_{12} interferes with the antimicrobial properties of aminoglycosides, along with the significant potential risk associated with these medications, suggest that physicians prescribing aminoglycoside therapy for more than a few days might find it prudent to coadminister vitamin B_{12}, preferably by intramuscular injection or possibly within a multivitamin-mineral supplement, with extended outpatient care. Research indicates that alpha-tocopherol may also provide a protective effect against gentamicin-induced otovestibular toxicity.[67] Further research is warranted to determine if concomitant use of these two nutrients might provide a synergistic beneficial effect in conjunction with aminoglycoside therapy, possibly through their activity against oxidative stress and free-radical–induced damage. Restoration of intestinal microbiota through oral intake of probiotic flora is also essential after use of any significant course of antibiotic medications and can be especially important to normalization of B_{12} status.

Anticonvulsant Medications, Including Phenobarbital, Phenytoin, and Valproic Acid

Evidence: Carbamazepine (Carbatrol, Tegretol), divalproex semisodium, divalproex sodium (Depakote), phenobarbital (phenobarbitone; Luminal, Solfoton), phenytoin (diphenylhydantoin; Dilantin, Phenytek), sodium valproate (Depacon), valproate semisodium, valproic acid (Depakene, Depakene Syrup).
Extrapolated, based on similar properties: Clorazepate (Tranxene), ethosuximide (Zarontin), ethotoin (Peganone), felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), levetiracetam (Keppra), mephenytoin, methsuximide (Celontin), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), piracetam (Nootropyl), primidone (Mysoline), topiramate (Topamax), trimethadione (Tridione), vigabatrin (Sabril), zonisamide (Zonegran).

Effect and Mechanism of Action

In general, anticonvulsants may cause vitamin B_{12} depletion or deficiency, at least in part from decreased absorption of cobalamin.[68] Anemia in individuals undergoing long-term antiepileptic therapy appears usually to derive from drug-induced folic acid and B_{12} deficiency. In vitro experiments with human promyelocytic leukemia cell line, HL60, suggest that one mechanism underlying some undesirable effects of long-term therapy with phenytoin may be a drug-related impairment of both folate and vitamin B_{12} uptake by certain cells, including hemopoietic and neural cells.[69] Homocysteine (Hcy) is a known convulsant agent and has been used experimentally to induce seizures. Antiepileptic drugs (AEDs, and possibly seizure disorders themselves) are also known to contribute to elevated plasma tHcy levels in many individuals, and drug-induced depletion of vitamin B_{12} and folic acid plays a significant role in that process.[70-73] Interactions between anticonvulsants and folic acid are well documented,[74-76] and drug-induced folic acid deficiency contributes to vitamin B_{12} deficiency.

Research

Findings from human trials investigating the potential for anticonvulsant medications to cause clinically significant vitamin B_{12} depletion and deficiency are mixed and, thus far, suggestive but inconclusive. Frenkel et al.[77] found that, even in

the absence of laboratory confirmation of anemia, individuals on long-term anticonvulsant therapy demonstrated significantly lower levels of vitamin B_{12} in their cerebrospinal fluid (CSF) compared with controls. A majority of symptomatic individuals demonstrated improved mental status and nerve function after several days of supplemental vitamin B_{12}, 30 μg daily. Subsequently, in a trial with 51 patients receiving treatment at an outpatient epilepsy clinic, Schwaninger et al.[78] found that long-term AED therapy, using carbamazepine (Tegretol), phenytoin (Dilantin), or phenobarbital, was associated with elevated plasma Hcy concentrations but had no measurable effect on serum levels of vitamin B_{12} compared with controls. In a study comparing 16 healthy children and 16 children with epilepsy who had been receiving carbamazepine for 1 to 4.5 years, Deda et al.[79] found lower mean serum level folic acid in the medicated group, although within normal limits, but no statistically significant difference in serum vitamin B_{12}. This same research team later published a paper showing no significant differences in serum vitamin B_{12} and folic acid concentrations in 26 children with epilepsy who had been receiving long-term valproate therapy, compared to 28 healthy children.[79] Although these findings may initially appear contradictory, such variance may be attributable to research design, the medications used, their dosage and duration, B_{12} assay methods, or other ancillary factors, including patient age and health status. Overall, the available evidence indicates that long-term therapy with the most commonly used AEDs (carbamazepine, phenytoin, phenobarbital, valproate) does not inherently induce significant declines in serum concentrations of vitamin B_{12}.

Early-onset cobalamin (Cbl) C/D deficiency is an inborn error of intracellular Cbl metabolism characterized by high plasma levels of methylmalonic acid (MMA), homocystine, and homocysteine. Biancheri et al.[80] studied 10 children with early-onset cobalamin C/D deficiency and reported epilepsy and electroencephalogram (EEG) abnormalities as prominent features associated with the early-onset type of combined methylmalonic aciduria and homocystinuria, possibly related to the pathologically and persistently high Hcy levels. Furthermore, within the emerging field of toxicogenomics, phenobarbital and other enzyme inducers are associated with distinct gene-expression profiles that influence how different medications affect individuals in divergent ways,[81] most likely including their adverse effects and impact on vitamin B_{12} and other nutrients.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The research available at this time indicates that anticonvulsant medications as a class do not consistently cause clinically significant patterns of vitamin B_{12} depletion, at least as indicated by the assay methods (usually serum levels) applied and the medications studied. Further research indicated in this important but until recently somewhat neglected area, especially given increased knowledge of the impact of B_{12} deficiency on neurological and psychiatric conditions and the elusive nature of detecting depletion patterns before the onset of overt pathological changes. Physicians prescribing anticonvulsant therapy may consider it judicious to measure urinary MMA levels, and/or recommend supplemental vitamin B_{12} to counter potential effects of drug-induced depletion patterns, despite the lack of strong evidence of regular occurrence, given the subtle and long-term implications of such a deficiency and the lack of toxicity or interference with the antiepileptic treatment associated with the nutrient. Furthermore, some nutritionally oriented health care professionals generally supplement with vitamin B_{12}, vitamin B_6, and folate in patients undergoing long-term anticonvulsant therapy as a preventive measure against increased Hcy plasma concentrations associated with seizure disorders, their treatment, and other sources of deficiencies of these nutrients. Periodic monitoring of fasting plasma Hcy levels in this patient population would also be prudent.

Antidepressants

Evidence: Amitriptyline (Elavil); combination drug: amitriptyline and perphenazine (Etrafon, Triavil, Triptazine); amoxapine (Asendin), citalopram (Celexa), clomipramine (Anafranil), desipramine (Norpramin, Pertofrane), doxepin (Adapin, Sinequan), fluoxetine (Prozac, Sarafem), imipramine (Janimine, Tofranil), nortriptyline (Aventyl, Pamelor), paroxetine (Aropax, Deroxat, Paxil, Seroxat), protriptyline (Vivactil), trimipramine (Surmontil).

Extrapolated, based on similar properties:

Selective serotonin reuptake inhibitor (SSRI) antidepressants: Escitalopram (S-citalopram; Lexapro), fluvoxamine (Faurin, Luvox), sertraline (Zoloft).

SSRI/SNRI antidepressants: Duloxetine (Cymbalta), venlafaxine (Effexor).

Interaction Type and Significance

Effect and Mechanism of Action

Although scientific understanding is incomplete and conclusive evidence is lacking, numerous mechanisms may account for research findings suggesting that adequate or high vitamin B_{12} levels may decrease susceptibility to depression and enhance response to antidepressant therapy through multiple mechanisms. Of first order is the intimate relationship between B_{12} and folate and the numerous linkages between these nutrients and neurotransmitters, emotional state, and general well-being. Low vitamin B_{12} (and folate) status may result in elevated Hcy levels and lead to exitotoxic reactions in the CNS that may enhance depression. Vitamin B_{12} is also necessary for endogenous formation of *S*-adenosylmethionine (SAMe), which has a known antidepressant action. Vitamin B_{12} may also play an important role in alleviating depression through its involvement in the synthesis of monoamine neurotransmitters such as serotonin and dopamine. Notably, some antidepressants invoke a mechanism of action involving inhibition of monamine metabolism. In a broader contextual perspective, the nutrient status of individuals with depression may be compromised by their life situations or as part of their depressive behavior. Lastly, the potential for B_{12} depletion/antagonism by some antidepressants also deserves consideration and further investigation.

Research

Individuals with depressive disorders have been characterized as more likely to have low levels of vitamin B_{12} and folate,[82-85] with a doubled risk of depression in elderly, physically disabled women with significant B_{12} deficiency. Tiemeier et al.[86] found that B_{12} deficiency, but not folate deficiency, is independently associated with depressive disorders.[86] However, Bjelland et al.[87] found no significant correlation between low plasma folate or B_{12} levels and depression without comorbid anxiety disorder in the general population.

Researchers have noted that individuals with low folate levels demonstrate a poor response to antidepressant therapy.[85,88,89] In a 4-week, randomized, placebo-controlled, double-blind clinical trial involving 14 elderly patients under treatment for major depression with cognitive dysfunction, Bell et al.[90] reported that subjects receiving small doses of vitamins B_1, B_2, and B_6 (10 mg each daily) demonstrated significantly better B_2 and B_6 status on enzyme activity coefficients and trends toward greater improvement in scores on ratings of depression and cognitive function, along with increased vitamin B_{12} levels and serum nortriptyline levels. Those receiving placebo (i.e., no B complex) also exhibited reduced B_{12} levels. Hintikka et al.[91] conducted a 6-month, "naturalistic prospective follow-up study" involving 115 outpatients (45 male and 70 female outpatients) being treated for depression using a range of antidepressive medications (citalopram, fluoxetine, paroxetine, tricyclics), most with some degree of active concomitant therapeutic relationship. No patients had a low vitamin B_{12} status at baseline (and 12% exhibited elevated initial B_{12} levels), and there was no correlation between severity of depression and baseline B_{12}. However, the participants who fully responded to treatment had the highest serum vitamin B_{12} levels at the beginning and end of the study, with that significance remaining after factoring out smoking, drinking habits, type of treatment, and family history.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Further epidemiological studies and larger, well-designed clinical trials are warranted to clarify the role of vitamin B_{12} (and folate) in depressive disorders. Pending such conclusive investigation, physicians prescribing antidepressant medications are advised to consider concomitant supplementation of vitamin B_{12}, preferably with folic acid, as a potential adjunctive therapy for the depression itself and as a possible means of enhancing therapeutic response to the pharmacological therapy. Close supervision and regular monitoring are warranted because nutrient supplementation has been observed to elevate medication levels in certain cases.

Bile Acid Sequestrants

Evidence: Cholestyramine (Locholest, Prevalite, Questran), colestipol (Colestid).
Extrapolated: Colesevelam hydrochloride (WelChol).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability:	Evidence Base:
4. Plausible	○ **Preliminary**

Effect and Mechanism of Action

Bile acid sequestrants, such as cholestyramine, decrease lipid digestion and absorption, as well as absorption of the fat-soluble vitamins and other nutrients, including vitamin B_{12}.[50,92-94] In particular, the intrinsic factor–cyanocobalamin complex appears to be strongly adsorbed by cholestyramine and colestipol, while cyanocobalamin itself may not be adsorbed by these antihypercholesterolemic resins.[95]

Research

Intrinsic factor–mediated binding of cyanocobalamin by bile acid sequestrants can occur but may not be clinically significant. In 1973, Coronato and Glass[92] reported depression of the intestinal uptake of radiovitamin B_{12} in the presence of cholestyramine. In a clinical trial involving 18 children with familial hypercholesterolemia, West and Lloyd[96] observed that prolonged treatment with cholestyramine was associated with a fall in mean serum folate concentration, as well as decreased mean serum concentrations of vitamins A and E and of inorganic phosphorus, but no significant changes in concentrations of serum iron, vitamin B_{12}, plasma calcium, or protein. In an in vitro investigation of cholestyramine and colestipol, Leonard et al.[97] found that both resins bound, to a high extent, vitamin B_{12}–intrinsic factor complex, folic acid, and iron citrate. In a related in vitro experiment, Teo et al.[98] found that dihydroxy bile acids (deoxycholic, glycodeoxycholic, taurodeoxycholic, glycochenodeoxycholic, and taurochenodeoxycholic), at concentrations found in duodenal juice, inhibit the binding of intrinsic factor to vitamin B_{12}, suggesting that vitamin B_{12} absorption might be reduced. These collective data suggest that bile acid sequestrants may inhibit B_{12} absorption, but that such effects are not usually measurable through serum B_{12} levels. Further human research is warranted using more sensitive measures of B_{12} status, such as urinary MMA, to determine how frequently clinically significant inhibition of absorption occurs, which patient populations are most susceptible to drug-induced depletion, and what compensatory measures, if any, might be appropriate.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Given the limitations of the available evidence, monitoring of vitamin B_{12} status, using a sensitive index, is prudent for patients using bile acid sequestrants, especially in "at-risk" populations. Supplementation with a multivitamin-mineral formulation may be judicious in preventing drug-induced depletion of B_{12} and other nutrients susceptible to decreased absorption; no adverse effects or interactions would be expected from such nutritional support.

Chloramphenicol

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**
◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probable:	Evidence Base:
2. Probable	○ **Preliminary**

Effect and Mechanism of Action

Chloramphenicol may reduce the absorption of vitamin B_{12}. It can also oppose the erythropoietic activity of B_{12} or iron in the treatment of anemia. Vitamin B_{12} may reduce or reverse adverse effects associated with chloramphenicol.

Research

Chloramphenicol may cause bone marrow depression and can oppose the erythropoietic activity of B_{12} or iron in the treatment of anemia.[99-101] Saidi et al.[100] reported that four patients receiving B_{12} therapy for pernicious anemia were all similarly refractory to treatment until chloramphenicol was withdrawn. "Very high daily doses" of pyridoxine and cyanocobalamin appear capable of reversing chloramphenicol-induced optic neuritis.[102]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing chloramphenicol therapy for an extended period are advised to monitor vitamin B_{12} (and iron) status, using a sensitive index, especially in at-risk populations. Prescribing moderate dosage levels of chloramphenicol (e.g., 25-30 mg/kg) can usually obtain efficacious effects against infections without introducing the risk of marrow depression, which usually does not occur unless serum levels rise to 25 µg/mL or higher[103]; alternative antibacterial agents could also be considered. Thus, chloramphenicol is rarely used in the United States at this time because of its rare but devastating complication of aplastic anemia. It is still used often in other countries, such as Mexico. Its use in the United States is almost always in the hands of infectious disease specialists in treatment of rare and highly antibiotic-resistant infections.

Supplementation with a multivitamin-mineral formulation may be judicious in preventing chloramphenicol-induced depletion of B_{12}. No adverse effects or interactions would be expected from such nutritional support. In the event that chloramphenicol causes optic neuritis, health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics can institute a collaborative response using high doses of pyridoxine and cyanocobalamin to reverse the condition.

Clofibrate and Related Fibrates

Evidence: Clofibrate (Atromid-S), fenofibrate (Lofibra, Tricor, Triglide).
Related but evidence against extrapolation: Bezafibrate (Bezalip), ciprofibrate (Modalim), gemfibrozil (Apo-Gemfibrozil, Lopid, Novo-Gemfibrozil).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **2. Probable**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Clofibrate impairs absorption of vitamin B_{12}.[104] Fenofibrate or other fibrates may have similar activity. Fenofibrate and bezafibrate are known causes of iatrogenic hyperhomocysteinemia. Gemfibrozil does not influence plasma Hcy in the same way because, unlike other fibrates, it does not bind and activate the peroxisome proliferator-activated receptors alpha (PPAR-α), which downregulate the renal cyclooxygenase-2 (COX-2) enzyme system.

Research

Concern has been raised that inhibition of vitamin B_{12} absorption by fibrates might contribute to hyperhomocysteinemia associated with these medications. Dierkes et al.[105] reported that serum Hcy significantly increases after therapy with fenofibrate or bezafibrate; no corresponding changes in folate and cobalamin concentrations were observed, although there was a slight but significant lowering of vitamin B_6 with fenofibrate. These authors postulated that this effect resulted from fenofibrate effects on renal function. Two years later, they published a second paper showing that in a crossover study with 22 hypertriglyceridemic patients, Hcy, creatinine, and cystatin-C were raised by fenofibrate but not by gemfibrozil, another fibrate, which does not affect renal function.[106] Thus, these medications may disrupt absorption of B_{12} and other nutrients, but it appears that nutrient depletion may not be the direct mechanism underlying fenofibrate-induced elevations in Hcy blood levels. Nevertheless, these studies demonstrate that coadministration of folic acid or a vitamin combination with fenofibrate can prevent most of the Hcy increase associated with fenofibrate. Further research is warranted to determine whether coadministration of vitamin B_{12}, folic acid and vitamin B_6 might lower Hcy in individuals taking gemfibrozil, clofibrate, or other fibrates.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Gemfibrozil is the only fibrate still in wide clinical use, and it is generally associated with fewer interactions and adverse effects than other fibrates. Although the interference of B_{12} absorption by clofibrate and possibly other fibrates appears undisputed, its impact on physiological levels and any consequent clinical implications remain unclear. However, the iatrogenic hyperhomocysteinemia associated with fenofibrate and bezafibrate aggravates the risk of atherosclerosis and cardiovascular risk in general, and as such, these medications present a strategic contradiction. Supplementation with vitamin B_{12}, folic acid, and vitamin B_6 is generally appropriate in individuals prescribed fibrates, except possibly gemfibrozil, particularly if Hcy levels are elevated.[107] No adverse effects or interference with the medications would be expected at usual dosages of these nutrients. Alternatively, treatment could be changed to gemfibrozil, an effective cardioprotective agent in patients with hypertriglyceridemia or low HDL (high-density lipoprotein) cholesterol, or both,[108] which does not increase plasma Hcy levels, or to an integrative approach to treatment of dyslipidemia incorporating regular exercise and restricted intake of high-glycemic carbohydrates, as well as nutritional support, including fiber, fish oil (EPA/DHA), pantethine, vitamin B_3 (niacin or inositol hexaniacinate), garlic, and beta-glucan.

Colchicine

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **2. Probable**
Evidence Base: ○ **Preliminary,** ▽ **Mixed**

Effect and Mechanism of Action

Colchicine interferes with vitamin B_{12} metabolism by reducing intrinsic factor–B_{12} receptors.[109-113] Neuropathies are a known adverse effect associated with colchicine use; research findings remain mixed and inconclusive as to whether such phenomena result from drug-induced B_{12} depletion or another, unknown mechanism.[109,113-116]

Research

The research findings on the clinical significance of colchicine's effect on the absorption of vitamin B_{12} is mixed, as is that pertaining to the mechanisms of colchicine-related neuropathies and their potential relationship to drug-induced B_{12} depletion. Variations in methods applied for assessing B_{12} status may play an important role in the respective findings of the various studies. For example, Ehrenfeld et al.[114] found no difference in serum B_{12} levels after long-term colchicine therapy in patients with recurrent polyserositis (familial Mediterranean fever).

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Despite uncertainty about the exact relationship between colchicine and vitamin B_{12} with regard to neuropathies, caution is indicated in elderly individuals taking colchicine and experiencing neurological symptoms. Pending well-designed clinical trials aimed at clarifying these questions, physicians prescribing colchicine are advised to coadminister vitamin B_{12} to counter the known drug-induced interference with absorption, particularly in patients at higher risk for B_{12} deficiency for other reasons, and even more so if any indications of neuropathy emerge; intramuscular (IM) injection may be necessary. Serum levels of B_{12} may still be normal during the initial phase of the onset of B_{12}-deficiency neuropathies; a more sensitive test, such as urinary MMA, may be necessary to detect a deficiency of gradual onset. In any event, the nontoxic nature of the nutrient presents a low-risk prophylactic option for the prudent physician to discuss with patients.

Histamine (H_2) Receptor Antagonists

Evidence: Cimetidine (Tagamet; Tagamet HB), famotidine (Pepcid RPD, Pepcid, Pepcid AC), ranitidine (Zantac).
Similar properties but evidence lacking for extrapolation: Nizatidine (Axid, Axid AR), ranitidine bismuth citrate (Tritec).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability:
3. Possible

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Histamine (H_2) receptor antagonists (H_2RAs) decrease secretion of gastric acid and pepsin by gastric parietal cells. Gastric acid and pepsin are required for the cleavage of vitamin B_{12} from animal protein-bound dietary sources. Thus, cimetidine, ranitidine, and related medications significantly impair liberation of dietary B_{12} from its protein binder during digestion. Further, intrinsic factor (IF), also produced by gastric parietal cells, is required for vitamin B_{12} absorption from the gastrointestinal (GI) tract.[117-119]

Research

Comparing the effect of cimetidine on the absorption of orally administered crystalline or food (egg yolk–bound) vitamin B_{12} in 13 patients, Salom et al.[117] observed that whereas absorption of crystalline B_{12} was normal and not significantly changed by cimetidine, the uptake of food-bound B_{12} decreased by a mean of 53% in all patients. These authors further noted that their findings indicated that cimetidine-induced B_{12} malabsorption would not be detected by the standard Schilling test.[117] Nevertheless, Walan and Strom[120] investigated the effect of continuous treatment with cimetidine (400 mg at night or twice daily) for 3 years and found no significant difference on plasma vitamin B_{12}, as well as weight, hemoglobin, plasma iron, plasma folate, and albumin; a slight decrease of plasma calcium was observed. They concluded that moderate and inconstant reduction of acidity over 24 hours, typical of twice-daily administration of those H_2 antagonists available in 1985, was unlikely to result in metabolic consequences. Later, in a randomized controlled prospective study, Thorens et al.[121] investigated the incidence of gastric and duodenal bacterial overgrowth in 47 outpatients with peptic disease being treated with omeprazole or cimetidine. After a 4-week treatment regimen, they found higher basal gastric pH and a significantly higher level of bacterial overgrowth in patients receiving omeprazole than in those receiving cimetidine. However, even with this significant disruption of the digestive tract's environment, serum concentrations of vitamin B_{12}, beta-carotene, and albumin were similar before and after treatment with both drugs.[121]

Kirch et al.[122] reported that ranitidine (300 mg daily) distinctly reduced protein-bound cobalamin absorption from a mean of 7.66% before ranitidine administration to 0.84% during treatment with ranitidine.

Overall, a consensus emerged starting in the 1980s that H_2RAs interfered with absorption of vitamin B_{12} from food sources, more so than from supplemental sources, and that consistent long-term use in at-risk populations posed a significant potential for clinically significant nutrient depletion. Short-term or intermittent use has generally been considered to have an inconsequential effect on nutrient absorption.[123,124] In particular, Aymard et al.[123] noted that hematological adverse effects attributable to H_2RAs are relatively uncommon, usually involving cimetidine, and that the inhibition of gastric secretion by the H_2RAs may theoretically contribute to the occurrence of cobalamin (or iron) malabsorption and deficiency anemia with long-term use.

The interaction of H_2RAs and other medications may also affect B_{12} status. For example, metformin decreases absorption of vitamin B_{12} and folic acid, and cimetidine decreases the elimination of metformin; therefore a reduced metformin dosage is usually recommended when these agents are combined.[125] The clinical implications of such multiple interactions have yet to be studied in any systematic manner in well-designed human trials, even though patients taking multiple pharmaceuticals may constitute the norm more than the exception among affected populations.

Report

In a case report, Ruscin et al.[126] described vitamin B_{12} deficiency in a 78-year-old nonvegetarian woman with symptomatic gastroesophageal reflux after long-term use (~4.5 years) use of H_2RAs, starting with cimetidine, and a proton-pump inhibitor. They noted a moderate decline in serum vitamin B_{12} concentration, from an initial normal serum level of 413 pg/mL to a low-normal level of 256 pg/mL after almost 2 years. However, on the latter occasion, MMA and Hcy, clinically important biochemical markers of B_{12}-dependent enzyme activity, were significantly elevated. These researchers then observed that MMA and Hcy concentrations decreased dramatically when oral replacement of vitamin B_{12} (1000 µg daily) was instituted. This response not only confirmed vitamin B_{12} deficiency, but also demonstrated that the woman was able to adequately absorb nonprotein-bound vitamin B_{12} from the GI tract, suggesting that her deficiency was a result of food-cobalamin malabsorption, and that the accumulation of MMA and Hcy was not a consequence of renal dysfunction.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although H_2RAs have not conclusively been shown to decrease IF secretion, studies have demonstrated a significant reduction in protein-bound vitamin B_{12} absorption secondary to decreased gastric acid and pepsin secretion in patients taking these drugs. Although this interaction probably lacks clinical importance during the short term, continuous use of these medications for more than 2 years could cause or contribute to vitamin B_{12} deficiency, including anemia, especially in patients with a history of poor nutrition and other causes of inadequate stores of vitamin B_{12}. Such impairment of vitamin

B_{12} absorption could be amplified for individuals also using antacids on a regular basis along with the H_2RAs. Further research is warranted into the effect of these medications on the function of gastric acid and pepsin in the initial step of the B_{12} absorption process and the clinical implications of any resulting impaired release of cobalamin from food protein.

Physicians prescribing H_2RAs are advised to monitor cobalamin status, preferably using a sensitive test, such as urinary MMA, and to coadminister supplemental vitamin B_{12} in individuals on H_2RA and/or proton pump inhibitor (PPI) therapy for an extended period, especially when other risk factors for deficiency are present. In the event that supplementation is determined to be necessary, a typical adult dose of 10 to 25 µg per day would be appropriate, a level commonly found in a B-complex vitamin or in many multivitamins. Given the likely mechanism of action involved, patients taking H_2RAs who are prone to or have developed a vitamin B_{12} deficiency will generally respond to oral supplementation, which does not require stomach acid to be absorbed.

Metformin and Related Biguanides

Evidence: Metformin (Dianben, Glucophage, Glucophage XR).
Extrapolated: Buformin, metformin combination drugs: glipizide and metformin (Metaglip), glyburide and metformin (Glucovance).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Coadministration Therapeutic, Not Requiring Professional Management**

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **2. Probable**
Evidence Base: ● **Consensus**

See Folic Acid monograph for further discussion.

Effect and Mechanism of Action

Biguanide therapy, particularly metformin, causes reduced vitamin B_{12} absorption and low serum total vitamin B_{12} and holotranscobalamin (B_{12}-TCII) levels by depressing intrinsic factor (IF) secretion[127] and through a calcium-dependent ileal membrane antagonism affecting B_{12}-IF complex uptake.[128] B_{12}-IF complex uptake by ileal cell surface receptors depends on calcium availability, and metformin specifically affects calcium-dependent membrane action; this effect can be reversed by supplemental calcium.

Research

Of patients who are prescribed metformin, conservatively 10% to 30% have evidence of reduced vitamin B_{12} absorption, accompanied by a decline in folic acid status and elevation of Hcy. An early study by Carpentier et al.[129] involving diabetic individuals determined that whereas biguanides depleted vitamin B_{12}, folic acid was not similarly affected. In a subsequent study involving nondiabetic male patients with coronary heart disease, Carlsen et al.[130] observed that metformin increases total serum Hcy levels and depletes vitamin B_{12} and sometimes folic acid. More recently, in a randomized, placebo-controlled trial involving 390 patients with type 2 diabetes, Wulffele et al.[131] found that 16 weeks of treatment with metformin reduces serum levels of vitamin B_{12} and folate, resulting in a modest increase in Hcy.[131] This pattern has been confirmed by Ting et al.,[132] who found "an increased risk of vitamin B_{12} deficiency associated with current dose and duration of metformin use despite adjustment for many potential confounders."

Caspary et al.[155] initially noted that the vitamin B_{12} malabsorption, pathological Schilling tests, and elevated fecal bile acid excretion observed with biguanides, particularly metformin, improved when the medication was discontinued or antibiotics were administered. They interpreted these findings to suggest that small intestinal bacterial overgrowth, leading to binding of the IF-B_{12} complex to bacteria, was responsible for the B_{12} depletion observed in diabetic patients receiving biguanide therapy. Subsequently, Adams et al.[127] surveyed 46 randomly selected diabetic patients on biguanide therapy and found that 30% demonstrated malabsorption of vitamin B_{12}, apparently by two different mechanisms. On withdrawal of the drug, normal absorption returned in only half of those with malabsorption. Using absorption tests with exogenous IF, these researchers further determined that biguanide-induced depression of IF secretion mediated the persistent malabsorption in most individuals of the latter group.[127] Finally, Bauman et al.[128] performed a comparative study in which type 2 diabetic patients who had been receiving sulfonylurea therapy were switched to metformin for 3 months, after which oral calcium supplementation was administered. Monthly serial measurements of serum total vitamin B_{12} and B_{12}-TCII revealed parallel declines in those taking metformin compared with controls. The observed depression of B_{12}-TCII was reversed by the introduction of oral calcium supplementation.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing metformin or other biguanides are advised to supplement vitamin B_{12}, folic acid, and calcium and regularly monitor folic acid and vitamin B_{12} levels.

Methotrexate

Methotrexate (Folex, Maxtrex, Rheumatrex)
See also Antifolates section in Folic Acid monograph.

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **1. Certain**
Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Given methotrexate's intentional interference with normal functioning of folic acid metabolism, problems with vitamin B_{12} deficiency can be expected. Further, vitamin B_{12} and folic acid work together to control homocysteine (Hcy) levels and prolonged methotrexate therapy may contribute to elevated Hcy levels.

Research

Investigators have found that patients taking methotrexate have lower B_{12} levels within RBCs than in controls, but that serum levels of B_{12} were not different. They concluded that folate depletion may be related to B_{12} deficiency in RBCs.[134]

Further, in an experiment using mice with mammary adenocarcinoma, Miasishcheva et al.[135] measured the effect of methylcobalamin on 3H-methotrexate uptake by tumor and normal tissues. They found a dose-related response in which methylcobalamin stimulated the rate of 3H-methotrexate influx into the tumor and small intestine, but did not change its influx into the spleen.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

In no circumstances is methotrexate-induced vitamin B_{12} deficiency considered important to the drug's therapeutic efficacy. However, because folate deficiency inherently results from methotrexate use, some support to counterbalance the unintentional adverse effects on vitamin B_{12} levels would appear valuable. Supplementation with vitamin B_{12} is harmless and indicated. Physicians prescribing methotrexate are advised to coadminister vitamin B_{12}. In such cases, supplementation is often up to or greater than 1000 µg of cobalamin per day orally or by IM injections. In cancer patients with known tumors, however, caution is warranted because malignant tumors are known to be avid for B_{12} and folate, which are rate-limiting nutrients for DNA synthesis. Although not an issue for noncancer applications of methotrexate, caution with use of B_{12} and folate at above RDA/DV levels in cancer patients is warranted, pending careful clinical trial investigation of this issue.

Well-designed human trials are warranted to investigate the extent and implications of B_{12} depletion by methotrexate, as well as therapeutic guidelines for compensatory supplementation, and to explore potential concomitant administration of methylcobalamin to enhance the activity of methotrexate, and possibly enable reduction of the medication's dosage and amelioration of associated adverse effects.

Nitrous Oxide

Nitrous Oxide (N_2O)

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
2. Possible

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Repeated or prolonged nitrous oxide (N_2O) anesthesia can inactivate vitamin B_{12} and thereby interferes with the activity of folic acid, particularly in susceptible individuals; Hcy levels in turn can become elevated.[136-139] In particular, research has shown that N_2O induces inactivation of methionine synthase.[140] Among many potential sequelae, N_2O's interference with normal B_{12} activity can also lead to megaloblastic hematopoiesis.[141,142]

It is worth noting that in the research design of many investigations, such as on the effects of methotrexate, N_2O is used to inactivate cobalamin.[135,143]

Research

A broad consensus exists as to the nature of the interaction between N_2O and vitamin B_{12}. However, opinions appear mixed and the evidence is seemingly inconsistent as to the clinical significance, frequency, and severity of this interaction and the variable potential for such occurrence in patients and health care providers. In an animal experiment, O'Leary et al.[144] observed a synergistic interaction between vitamin B_{12} deficiency and N_2O exposure when they compared the bone marrow cells of rats raised on a B_{12}-deficient or B_{12}-sufficient diet and then exposed or not exposed to N_2O for 3 hours. In a study of urinary excretion of formic acid and formiminoglutamic acid (FIGLU) in surgical patients exposed to isoflurane alone or combined with N_2O, Koblin et al.[140] observed only a small, transient increase in the FIGLU-to-creatinine ratio in some patients that peaked at the end of anesthetic exposure and returned toward control levels by the first day after anesthesia and surgery. These authors concluded that "although an occasional patient may prove highly susceptible to and develop signs of severe vitamin B_{12} and folic acid deficiency after exposure to N_2O, our findings suggest that this is a rare event." Ermens et al.[138] reported measurable changes in Hcy and folate plasma and urine levels indicative of cobalamin inactivation during N_2O anesthesia. In a review article, Flippo and Holder[139] noted a pattern of neurological degeneration associated with N_2O anesthesia in patients with vitamin B_{12} deficiency.

However, Salo et al.[141] gathered peripheral blood samples from eight anesthetists and seven internists in a survey of potential occupational health hazard to operating theater personnel chronically exposed to trace N_2O concentrations. They reported that no evidence of definite signs of B_{12}-N_2O interaction could be observed in peripheral blood counts and films, serum vitamin B_{12}, and plasma and erythrocyte folate concentrations.[141] The issue of how this interaction might affect individuals abusing N_2O has not been addressed in a systematic or direct manner and deserves consideration as a potential area of concern.

Reports

Both Amos et al.[145] and Nunn et al.[142] reported cases of individuals in whom N_2O anesthesia induced B_{12}-related adverse effects, including megaloblastic bone marrow changes, which were reversed by administration of folic acid or folinic acid.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although the mechanism of nitrous oxide's effect on vitamin B_{12} activity is generally recognized and agreed on, the research on the topic has come to differing conclusions as to the probability of clinically significant adverse effects. Nevertheless, an analysis of these findings reveals a clear and consistent pattern indicating that short-term or occasional administration of N_2O, or even repeated minimal exposure over an extended period in the case of medical personnel, is unlikely to present a significant risk of substantive adverse effects on B_{12} (and folic acid) levels or activity. Overall, the incidence of severe adverse reactions appears to be rare. However, repeated or prolonged exposure to N_2O anesthesia in individuals with preexisting B_{12} (or folate) deficiency, significantly compromised general health status, pharmacogenomic limitations in detoxification functions, or other risk factors can create a situation of meaningful risk for a moderate to severe adverse reaction of a transient or cascading nature.

Evidence is lacking to support a recommendation for routine supplementation by medical or dental staff regularly

exposed to N_2O. However, the need for B_{12} and folate administration should be considered for individuals who have a recent history of, or are known to be currently engaged in, the habitual use of N_2O as a recreational drug. Urinary MMA level determination would be a useful monitoring test in both situations.

Normally, most patients with normal vitamin B_{12} levels who undergo short-duration N_2O anesthesia (<2 hours) do not require supplementation. Nevertheless, prophylactic supplementation with vitamin B_{12} and folate can provide a relatively certain preventive measure, with little or no risk of (additional) adverse effects, for patients who will undergo N_2O anesthesia for several hours, especially if these individuals are in poor health, have indications of compromised B_{12} status, or demonstrate other cause for elevated risk.[145] Some health care professionals trained and experienced in nutritional therapies within an integrative context recommend 100 µg of vitamin B_{12} and 1000 µg folic acid, starting 1 week before and continuing for 1 week after prolonged N_2O exposure.

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCep. 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50)
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
3. Possible

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

The use of oral contraceptives (OCs), especially those with higher estrogen content, has been consistently associated with decreased levels of vitamin B_{12}.[146-148]

Research

Several decades of evidence indicate, and a broad consensus of researchers and reviewers recognize and agree, that OCs can cause a biochemical deficiency of vitamin B_{12} and other nutrients.[109,148-151] The clinical implications of this probable interaction are uncertain at this time, but the conventional judgment expressed in the literature postulates that direct adverse effects of clinical significance are unlikely in most cases. Nevertheless, in a 1975 letter, Briggs[152] stated that requirements for riboflavin, thiamine, B_{12}, B_6, and tocopherols may be increased by the use of OCs, whereas niacin and possibly vitamin A requirements may be reduced, and that normalization in nutrient status "can be effected fairly quickly by use of a daily multivitamin," which he recommended as a "routine prophylactic prescription." He further noted that "clinical signs of hypovitaminosis include depression, susceptibility to infections, and skin signs, all of which were found in users of oral contraceptives in an epidemiological survey of 46,000 women in Great Britain."[152] Megaloblastic anemia has been linked to OC use, although this has been infrequently observed and reported.

Wertalik et al.[146] compared B_{12}-binding proteins and serum folate concentration in 20 women who had been taking OCs for 2 to 60 months, 26 women in the third trimester of pregnancy, and 23 control women. They found that mean serum vitamin B_{12} levels were 221 pg/mL in OC users (vs. 372 pg/mL in controls, i.e., 40% lower), and that half these women had serum B_{12} levels below normal limits (i.e., <200 pg/mL). Generally, women in the OC group demonstrated normal B_{12}-binding protein capacity and RBC levels of vitamin B_{12}. The mean for serum folic acid was within normal range among OC users, but 30% had levels below normal (4 ng/mL). Evidence of anemia or hypersegmentation was lacking in any of these women.

However, in regard to adverse cardiovascular effects of OCs, it is also important to note that vitamin B_{12} is essential for the metabolism of the atherogenic amino acid homocysteine. Well-designed clinical trials are warranted to investigate this deeper pattern of relationship between exogenous estrogen and cardiovascular risk that may be mediated by Hcy, or reflected in Hcy levels, and may be selectively detrimental to certain individual possessing as-yet unknown pharmaco/toxicogenomic characteristics involving estrogen conjugation and influenced by nutrient depletion.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Women taking OCs could reduce potential adverse effects on their cobalamin levels through supplementation with vitamin B_{12}. Although supplemental use of vitamin B_{12} is not usually considered necessary for most of the population, the suggested dose of cobalamin in vegans is 2 to 3 µg per day, and higher levels in the range of 50 to 200 µg per day may be indicated for OC users. Supplementation with vitamin B_{12} (and folate) may also reduce tendencies toward or the degree of hyperhomocysteinemia, particularly in women with compromised liver function, symptoms of an estrogen-dominance pattern, or genomic susceptibility. Physicians prescribing OCs are advised to discuss potential benefits from vitamin B_{12} (and folic acid) supplementation with their patients.

Para-Aminosalicylic Acid

Para-Aminosalicylic Acid (4-aminosalicylic acid, 4-ASA, aminosalicylic acid, *p*-aminosalicylic acid, PAS; Paser).

Para-aminosalicylic acid (PAS) is a medication used in the treatment of tuberculosis, but it is rarely prescribed anymore, except for some of the multidrug-resistant strains. PAS is known to cause vitamin B_{12} malabsorption and depletion.[153] When PAS is used clinically, it would be prudent to coadminister B_{12}, monitoring urinary MMA to determine sufficiency of nutrient support.

Pemetrexed

Pemetrexed (Alimta); combination drug: pemetrexed and cisplatin.
See also Antifolates section in Folic Acid monograph.

Interaction Type and Significance
☼ Prevention or Reduction of Drug Adverse Effect
⊕⊕ Beneficial or Supportive Interaction, with Professional Management

Probability:
2. Probable

Evidence Base:
◉ Emerging, possibly
● Consensus

Effect and Mechanism of Action
Pemetrexed is a multitargeted antifolate/antimetabolite chemotherapeutic agent that inhibits several folate-dependent enzymes, including thymidylate synthase, dihydrofolate reductase, and glycinamide ribonucleotide transformylase, and causes elevation of plasma total homocysteine (tHcy) levels. Sporadic, severe myelosuppression, with GI toxicity, is a life-threatening and predictable, if infrequent, adverse effect associated with antifolates as a class.

Research
Pretreatment plasma tHcy and, to a lesser extent, MMA can be used as vitamin deficiency markers to predict nutrient depletion and severe toxicity, such as severe thrombocytopenia and neutropenia, from pemetrexed-based therapy.[154] Niyikiza et al.[155] report that concomitant folic acid and vitamin B_{12} can reduce plasma tHcy levels and improve the safety profile for pemetrexed, without reducing and possibly increasing its efficacy.

Vogelzang and associates[156] conducted a clinical trial involving 456 chemotherapy-naive patients with malignant pleural mesothelioma, which also studied the use of concomitant folate and vitamin B_{12} as part of a Phase III study of pemetrexed in combination with cisplatin versus cisplatin alone. After an initial 117 patients had enrolled, folic acid and vitamin B_{12} were added to reduce toxicity, resulting in a significant reduction in toxicities in the pemetrexed/cisplatin arm. Folic acid was administered orally (350-1000 µg daily) beginning 1 to 3 weeks before the initial chemotherapy treatment and continued throughout the study. Vitamin B_{12} (1000 µg) was administered intramuscularly starting 1 to 3 weeks before the first dose of chemotherapy and repeated every 9 weeks while each patient was receiving the study therapy. Coadministration of folate and vitamin B_{12} with pemetrexed plus cisplatin treatment resulted in superior survival time, time to progression, and response rates compared with treatment with cisplatin alone. These researchers concluded that the addition of folic acid and vitamin B_{12} to the chemotherapeutic regimen significantly reduced toxicity without adversely affecting treatment efficacy and survival time.[156]

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Physicians prescribing pemetrexed, or related antifolates, alone or in combination with cisplatin, are advised to identify patients at risk of toxicity before initiating treatment, by measuring plasma tHcy and administering concomitant folic acid and vitamin B_{12}, as indicated, to decrease Hcy levels through vitamin supplementation, enhance the drug safety profile, reduce drug toxicity, and possibly improve efficacy.

Proton Pump Inhibitors (PPIs)

Evidence: Omeprazole (Losec, Prilosec).
Extrapolated, based on similar properties: Esomeprazole (Nexium), lansoprazole (Prevacid, Zoton), pantoprazole (Protium, Protonix, Somac), rabeprazole (AcipHex, Pariet).

Interaction Type and Significance
≈≈≈ Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management
☼ Prevention or Reduction of Drug Adverse Effect

Probability:
3. Possible

Evidence Base:
● Consensus

Effect and Mechanism of Action
Omeprazole binds in its active form in the parietal cells of the gastric mucosa with H^+,K^+-ATPase. This enzyme is responsible for the pumping of protons into the gastric lumen in exchange for potassium ions ("proton pump"). By design, omeprazole leads to a dose-dependent inhibition of gastric acid secretion. This in turn will interfere with cleavage of vitamin B_{12} from dietary proteins and will decrease protein absorption. Consequently, concern has been raised that prolonged omeprazole therapy could be responsible for a cobalamin deficiency from malabsorption of protein-bound dietary vitamin B_{12}.[157,158] Absorption of protein-bound cobalamin is further impaired in patients being treated for Zollinger-Ellison syndrome and individuals with atrophic gastritis, often associated with omeprazole therapy, especially in patients with *Helicobacter pylori* infections.[159,160]

Research
Reduced serum vitamin B_{12} levels have been documented occasionally in relation to long-term treatment with a proton pump inhibitor (PPI) in selected groups of patients. Several studies have found that omeprazole interferes with the absorption of vitamin B_{12} from food sources. Long-term omeprazole treatment leads to significant decreases in serum vitamin B_{12} but not folate levels.[120,161-163] These results suggest patients treated with H^+, K^+-ATPase inhibitors such as omeprazole should have vitamin B_{12} levels monitored regularly, via serum levels or as urinary MMA. The Schilling test will not detect malabsorption of food-bound cobalamin. However, other researchers, such as Koop,[164] have come to different conclusions. In general, the available evidence indicates that PPIs do not promote the development of pernicious anemia.

Schenk et al.[159] evaluated serum cobalamin levels and performed histopathological scoring of corpus biopsy specimens in 49 *H. pylori*–positive patients before and after omeprazole treatment for gastroesophageal reflux disease (GERD). Although none had signs of atrophic gastritis at inclusion, 15 patients (33%) had developed atrophic gastritis, nine of whom had moderate to severe atrophy at follow-up. Although no change was observed in the median serum cobalamin level in the 34 patients without atrophy, a decrease in cobalamin was seen from 340 at baseline to 285 at follow-up in the 15 patients who developed atrophy. These findings confirmed the hypothesis that development of atrophic gastritis during omeprazole treatment in *H. pylori*–positive GERD patients is associated with a decrease of serum vitamin B_{12} levels.[159] Subsequently, Shuval-Sudai and Granot[11] surveyed 133 supposedly healthy, non–vitamin B_{12}–deficient adults and found that the prevalence of *H. pylori* seropositivity was significantly higher among subjects with borderline (>145-180 pg/mL) or low-normal (>180-250 pg/mL) serum vitamin B_{12} levels than among those with vitamin B_{12} greater than 250 pg/mL.

As it alters the gastric environment, acid suppression also increases the risk of intragastric overgrowth of non–*H. pylori* bacterial species and formation of *N*-nitrosamines.[121,165] In chronic atrophic gastritis, atrophy of the stomach glands

leads to intrinsic factor deficit, with consequent failure to absorb vitamin B_{12} and gastric achylia, which predisposes to *Giardia* infection, which in itself leads to further depletion of vitamin B_{12}.[166]

Sagar et al.[167] investigated the role of *S*-mephenytoin hydroxylase, a polymorphic cytochrome P450 (CYP) enzyme, identified as CYP2C19, which catalyzes the metabolism of omeprazole and some other drugs in the effect on serum vitamin B_{12} levels during long-term treatment with omeprazole. No difference in B_{12} levels was found between heterozygous (wt/mut) and homozygous (wt/wt) in 111 patients after receiving one dose of 20 mg omeprazole. However, they found that the CYP2C19 polymorphism significantly affected serum vitamin B_{12} levels in patients on omeprazole therapy for more than 1 year.[167] Such findings strongly suggest that genotyping of CYP2C19 may be appropriate for patients in need of long-term treatment with omeprazole or other PPIs. Use of PPIs that do not depend primarily on 2C19 for metabolic clearance would be preferable in those patients found to have mutations in the gene encoding the 2C19 phase I hepatic enzyme, so as to avoid potentially excessive drug levels.

Reports

Bellou et al.[168] reported a case of cobalamin deficiency with megaloblastic anemia in a patient who received omeprazole (40-60 mg daily) for 4 years as treatment for a gastroesophageal reflux (GER) complicated by peptic esophagitis. Even though the Schilling test was normal (13%) with crystalline cobalamin, it was at 0% with cobalamin-labeled trout meat, and serum vitamin B_{12} was dramatically decreased at 80 pmol/L. Intramuscular treatment with cobalamin restored normal hematological status of B_{12}.

In a case report, Ruscin et al.[126] described vitamin B_{12} deficiency in a 78-year-old nonvegetarian woman with symptomatic GER after long-term use (~4.5 years) of histamine (H_2) receptor antagonists, starting with cimetidine, and a PPI. They noted a moderate decline in serum vitamin B_{12} concentration, from an initial normal serum of 413 pg/mL to a low-normal level of 256 pg/mL after almost 2 years. However, on the latter occasion, MMA and Hcy, clinically important biochemical markers of B_{12}-dependent enzyme activity, were significantly elevated. These researchers then observed that MMA and Hcy concentrations decreased dramatically when oral replacement of vitamin B_{12} (1000 μg daily) was instituted. This response not only confirmed vitamin B_{12} deficiency, but also demonstrated that the woman was able to adequately absorb nonprotein-bound vitamin B_{12} from the GI tract, suggesting that her deficiency was a result of food-cobalamin malabsorption, and that the accumulation of MMA and Hcy was not a consequence of renal dysfunction.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing omeprazole or other PPIs are advised to monitor their patient's B_{12} status regularly and, as indicated, administer concomitant vitamin B_{12} supplementation (10-50 μg/day orally) or IM injection. Supplemental forms of B_{12} do not require stomach acid to achieve proper absorption and protect against drug-induced vitamin depletion. Large oral doses (at least 1 mg daily) also bypass the need for intrinsic factor to be absorbed adequately to correct a B_{12} deficiency.

Well-designed clinical trials are warranted to evaluate the effect of omeprazole and related PPIs on B_{12} absorption over an extended follow-up period to determine the clinical significance of omeprazole-associated vitamin B_{12} deficiency and possibly identify patients at increased risk for deficiency. Physicians prescribing PPIs are advised to consider the possibility of dietary vitamin B_{12} malabsorption in patients receiving long-term PPI treatment and presenting with signs and symptoms of deficiency. Monitoring of B_{12} status using a sensitive index, such as urinary MMA, is critical in preventing the potential clinical complications of PPI-associated vitamin B_{12} deficiency. Individuals with the CYP2C19 polymorphism (poor metabolizers of omeprazole), elderly patients with poor dietary intake of vitamin B_{12}, individuals with impaired vitamin B_{12} stores, and those with certain GI disorders are at increased risk of adverse drug effects and in greater need of nutrient support. Since omeprazole became available without a prescription, there is a greater need for careful history taking of over-the-counter (OTC) medication use, as well as awareness of this potentially devastating complication in the at-risk population by all health care practitioners.

Zidovudine (AZT) and Related Antiretroviral Agents, Reverse-Transcriptase Inhibitor (Nucleoside)

Evidence: Zidovudine (azidothymidine, AZT, ZDV, zidothymidine; Retrovir).
Extrapolated, based on similar properties: Abacavir (Ziagen), didanosine (ddI, dideoxyinosine; Videx); dideoxycytidine (ddC, zalcitabine; Hivid), lamivudine (3TC, Epivir), stavudine (D4T, Zerit), tenofovir (Viread); zidovudine combination drugs: zidovudine and lamivudine (Combivir); abacavir, lamivudine, and zidovudine (Trizivir).

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Individuals infected with HIV tend to be at greater risk of compromised vitamin B_{12} status, and these medications may be associated with decreased B_{12} levels.

Research

Subnormal serum B_{12} levels appear to be common among individuals infected with HIV, even at early asymptomatic stages,[169] but particularly among those in advanced stages of AIDS. Furthermore, in several placebo-controlled studies, macrocytosis, anemia, and granulocytopenia were the most significant adverse effects associated with zidovudine use, especially among patients with advanced, symptomatic HIV disease. Significant anemia most often occurred after 4 to 6 weeks of therapy and in many cases required dose adjustment, discontinuation of zidovudine, and/or blood transfusions.

In an early study of azidothymidine (AZT) toxicity, Richman et al.[170] found that HIV-infected individuals with low vitamin B_{12} levels were more likely to develop anemia and other blood-related adverse effects after taking AZT.[170] In 1993, Snower and Weil[171] studied 100 consecutive inpatients in a large metropolitan urban hospital with macrocytosis and found that 44% were patients with AIDS being treated with zidovudine. In a descriptive cross-sectional survey involving 200 HIV-infected individuals, Paltiel et al.[172] found subnormal serum B_{12} levels in 61 subjects (30.5%) and observed

that malabsorption of vitamin B_{12}, as evidenced by abnormal Schilling tests, was more likely among patients with more advanced HIV disease or GI symptoms, but was not necessarily associated with low B_{12} levels. In a 1995 prospective, randomized study, Falguera et al.[173] determined that concomitant administration of vitamin B_{12} and folinic acid did not significantly prevent or reduce AZT-induced bone marrow suppression in most treated individuals.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing AZT or related retroviral therapy are advised to monitor the nutritional status of HIV-infected patients and discuss potential benefit from supplementation with vitamin B_{12} and folate. Regular monitoring of nutritional status and frequent blood counts are strongly recommended in patients with symptomatic HIV disease taking zidovudine. For asymptomatic HIV-infected individuals and patients with early HIV disease, most of whom have better marrow reserve, blood counts may be obtained less frequently, depending on the patient's overall status. If anemia or granulocytopenia develops, dosage adjustments may be necessary. In the event that supplementation is determined to be necessary, a typical adult dose of 10 to 25 μg daily, or 1000 to 1500 μg monthly, might be beneficial.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Aminosalicylates

Mesalazine (5-aminosalicylic acid, 5-ASA, mesalamine; Azacol, Canasa, Ipocal, Pentasa, Rowasa, Salofalk), para-aminosalicylic acid (4-aminosalicylic acid, 4-ASA, aminosalicylic acid, *p*-aminosalicyclic acid, PAS; Paser).

Aminosalicylates may reduce absorption of vitamin B_{12}.[174]

See also Para-aminosalicylic Acid.

Antibiotics, Particularly Cycloserine and Erythromycin

Cycloserine (Seromycin), erythromycin oral (EES, EryPed, Ery-Tab, PCE Dispertab, Pediazole).

The effects of antibiotics on vitamin B_{12} metabolism and function constitute an area of interactions research that has often been alluded to but rarely investigated in a direct and systematic manner. Many antibiotics are recognized to decrease absorption, reduce endogenous synthesis, and increase elimination of vitamin B_{12} and many other nutrients.[50,175,176] Some antibiotics rely on mechanisms of action that interfere with B_{12} metabolism (e.g., membrane transport) within bacterial cells.[177] Eradication of healthy intestinal bacterial flora and disruption of gut ecology by antimicrobials can reduce or eliminate the endogenous synthesis of B_{12} by symbiotic intestinal microbiota.[51,52] Restoration of intestinal microbiota through oral intake of probiotic flora is essential after use of any significant course of antibiotic medications and can be especially important to normalization of B_{12} status. Conversely, in some infections characterized by severe mucosal lesions and subsequent malabsorption, antibiotic therapy can help restore healthy B_{12} absorption.[178] Likewise, Crohn's disease patients who either have involvement or have had resection of the terminal ileum are at high risk of developing B_{12} deficiency because this is the site of absorption of the B_{12}–intrinsic factor complex.

Further research into the effects of antibiotics on vitamin B_{12} is warranted to clarify the particular mechanisms and outcomes of such interactions and enable formulation of guidelines for clinical practice. However, this potential for drug-induced deficiency may be more of an issue for vitamin K than for B_{12}, given the 3-year stores (or longer) of B_{12}, the 3 to 6 μg per day requirement, and the ubiquity of the vitamin in nonvegan diets.

Methyldopa

Methyldopa (Aldomet); combination drugs: methyldopa and chlorothiazide (Aldoclor), methyldopa and hydrochlorothiazide (Aldoril).

Methyldopa use can reduce vitamin B_{12} levels, potentially leading to a vitamin B_{12} deficiency, and may interfere with B_{12} metabolism.[179] Supplementation of vitamin B_{12} at moderate levels of 10 to 25 μg per day can counteract this tendency to depletion with no significant risk of adverse effects. The clinical implications of this potential interaction may be considered negligible/improbable, because methyldopa is rarely used anymore as an antihypertensive medication, being primarily employed in the treatment of pregnant women with hypertension, since it appears to be one of the safest antihypertensives for use in pregnancy.

Simvastatin

Simvastatin (Zocor).

In a preliminary clinical trial the coadministration of simvastatin (80 mg/day) and a combination of folic acid (2 mg/day) and vitamin B_{12} (0.8 mg/day) produced both serum lipid changes (with reductions in low-density lipoprotein cholesterol) and reductions in homocysteine. The combination group and simvastatin-alone group experienced similar serum lipid changes, and the combination group and vitamins-alone group experienced similar homocysteine reductions. Furthermore, no detectable antagonistic effect was observed when simvastatin and folic acid/vitamin B_{12} were administered concomitantly.[180] Further research with well-designed clinical trials is warranted for this novel approach to the multiple needs of prevention and treatment of cardiovascular disease using integrative approaches combining conventional pharmacology and nutritional therapeutics.

NUTRIENT-NUTRIENT INTERACTIONS

Alcohol

Excessive alcohol intake may reduce absorption of vitamin B_{12}.

Calcium

As previously discussed, increased intake of calcium can reverse vitamin B_{12} malabsorption induced by metformin.[128]

Folic Acid

Vitamin B_{12}, folic acid, and vitamin B_6 work together in a broad range of physiological functions, including controlling homocysteine levels. Supplementation with folic acid may mask a deficiency of vitamin B_{12}. Testing of B_{12} status by a physician is appropriate whenever anemia is suspected, and the combined supplementation of folic acid and B_{12} is usually advisable.

Folic acid deficiency, drug-induced or otherwise, can induce a deficiency of vitamin B_{12}. However, large doses of folic acid, given continuously, may reduce blood levels of vitamin B_{12}.

Potassium Chloride, Sustained/Controlled-Release Medications

Potassium administration can alter the amount of acid in the stomach and thereby inhibit the absorption of vitamin B_{12}.[181] Physicians prescribing slow-release potassium chloride may

find it judicious to supplement these patients with vitamin B_{12}, with separaton of intake.

Vitamin B_6

Vitamin B_{12} functions in concert with vitamin B_6 and folic acid in a broad range of physiological functions, including controlling homocysteine levels.

Vitamin C

Some sources suggest that vitamin C may damage or diminish the effectiveness of vitamin B_{12} if taken together. This interaction may be prevented by not taking large doses of vitamin C within 1 hour of oral vitamin B_{12} intake.

Vitamin D

A synergistic interaction between mecobalamin (B_{12}) and vitamin D appears to be involved in reducing the risk of hip fracture among stroke patients, with homocysteine as a predictive factor.[182,183]

The 183 citations for this monograph, as well as additional reference literature, are located under Vitamin B_{12} on the CD at the back of the book.

Vitamin C (Ascorbic Acid)

Nutrient Names: Vitamin C, ascorbic acid.
Synonyms: Antiscorbutic vitamin, ascorbate, ascorbic acid, ascorbyl palmitate, calcium ascorbate, cevitamic acid, chromium ascorbate, dehydroascorbic acid (DHA), isoascorbic acid, magnesium ascorbate, manganese ascorbate, molybdenum ascorbate, potassium ascorbate, sodium ascorbate, zinc ascorbate; Ester-C.
Related Substances: Acerola, rose hips.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Acetaminophen ⊕⊕/⊕ X/X	Concomitant intake of vitamin C can competitively inhibit the conjugation of acetaminophen with sulfate and increase the apparent biological half-life of acetaminophen, thus potentially increasing risk of acetaminophen-induced hepatotoxicity. Conversely, esters of ascorbic acid may reduce reactive intermediate back to parent compound such that hepatic ascorbate can protect against acetaminophen-induced hepatotoxicity. L-Ascorbic acid esters may reduce hepatic glutathione (GSH) depletion and facilitate regeneration. Not fully understood or adequately researched, but supervised coadministration of vitamin C with acetaminophen may enable reduced drug dosages and help protect against hepatotoxicity.	Consider vitamin C during acetaminophen therapy. Monitor liver enzymes with chronic acetaminophen use.
Acetylsalicylic acid (ASA, aspirin) Salsalate ☼/≈≈≈/⊕ X/X	Aspirin and salicylic acid can increase urinary excretion of vitamin C, lower leukocyte ascorbic acid levels, and decrease its metabolic availability. Gastric mucosa stores ascorbic acid, which is important in protecting epithelial cells, particularly against gastric erosion and hemorrhage. Compromised nutritional status can increase risk of adverse drug effects. Vitamin C may reduce gastric mucosal damage and gastric toxicity induced by ASA-generated free radicals. However, research findings have been mixed, and further study is warranted. Coadministration of vitamin C and other antioxidants may also potentiate aspirin's antiaggregative effects.	Watch for nutritional deficiencies in patients on long-term aspirin therapy and promote nutrient-rich diet. Consider ascorbic acid coadministration especially with potential ascorbic acid depletion.
Antihypertensive medications ⊕⊕	Enhanced levels of ascorbic acid may play a protective role against reactive oxygen species associated with essential hypertension and endothelial dysfunction. Concomitant intake of hypertensive medications and vitamin C may be beneficial in blood pressure management. Strong evidence is lacking and more research is needed. However, coadministration is unlikely to introduce any significant risks and may reduce cardiovascular risk and support therapeutic outcomes.	Consider vitamin C during antihypertensive therapy. Monitor regularly. Promote patient self-management of blood pressure and diet high in nutrient-rich vegetables and fruits.
Chemotherapy Radiotherapy X X X/⊕ X/X X/☼/≈≈	Coadministration of vitamin C, as with other antioxidants, may enhance the therapeutic effects of chemotherapy but, particularly if unsupervised and poorly timed, may interfere with radiotherapy and some forms of chemotherapy, particularly when free radicals are primary mechanism of action. Concomitant ascorbic acid beyond nutritional levels is controversial and, if indicated, demands close management by experienced clinicians. Direct research is limited and findings have been mixed. Generalized conclusions are inherently inadequate given the diversity of patients, pathologies, and medications. Further study through well-designed trials is warranted.	Unsupervised coadministration of high-dose vitamin C generally contraindicated. Coordinated care using high doses of intravenous ascorbic acid may be beneficial with experienced clinicians.
Cimetidine Histamine (H_2) receptor antagonists (H_2RAs) ☼	Cimetidine can cause decrease in serum hydrocortisone concentrations by binding to cytochrome P450, covering active heme group, and impairing hydroxylation reactions involved in human steroidogenesis. Preliminary evidence indicates that ascorbic acid, by an unknown mechanism, can prevent such a cimetidine-induced decrease in CYP450 activity and may normalize serum hydrocortisone concentration.	Coadministration of ascorbic acid before or with abdominal surgery may help mitigate adverse effects of cimetidine on cortisone levels.
Corticosteroids, oral ⊕⊕/≈≈/◇≈≈/☼	Ascorbic acid is essential in biosynthesis and metabolic regulation of certain steroid hormones, and its administration can increase serum hydrocortisone concentrations, particularly when steroidogenesis is inhibited. However, exogenous hydrocortisone can inhibit cellular uptake of ascorbic acid, impair its normal accumulation in adrenal tissues, and increase urinary excretion. Coadministration of ascorbic acid with glucocorticoids may enhance their therapeutic activity and reduce adverse effects of extended use, including vitamin C depletion. Research is limited but further study is warranted. Adverse effects are unlikely with clinical management.	Consider coadministration of ascorbic acid with long-term glucocorticoid therapy.
Cyclosporine ☼/≈≈/⊕ X/X	Coadministration of vitamin C, and possibly other antioxidants, with cyclosporine may reduce adverse effects without decreasing therapeutic efficacy. However, drug dose needs to monitored closely and possibly reduced because vitamin C could enhance bioavailability and decrease the clearance and steady-state	Consider concomitant ascorbic acid. Supervise closely and monitor drug levels regularly.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
	volume of drug's distribution. Further research warranted given limited knowledge of mechanisms involved and clinical implications.	
Desferoxamine Chelating agents ⊕✗/⊕⊕	Vitamin C can enhance absorption of nonheme iron, so concomitant intake of iron and vitamin C could theoretically increase risk of iron overload in certain predisposed individuals. Ascorbic acid modulates iron transport and storage, but increased iron levels can reduce blood levels of ascorbic acid through oxidation. Coadministration of vitamin C with desferoxamine can enhance iron excretion. However, rare complications have been reported due to exacerbation of toxic drug effects; although increased oxidation is suspected, no mechanism has been confirmed in humans. Research limited and further study needed.	Intravenous vitamin C may increase iron excretion by deferoxamine. Close supervision and monitoring are warranted, particularly in patients with cardiac disease.
Disulfiram ☼/⊕	Vitamin C may prevent (orally) or reduce severity (intravenously) of acetaldehyde toxicity associated with disulfiram-alcohol reactions. Coadministration can enhance therapeutic efficacy by reducing adverse effects and supporting drug compliance.	Use of vitamin C and related nutrients established in critical care of disulfiram toxicity; proper training required. Preventive use may be beneficial.
Erythropoiesis-stimulating agents ⊕⊕/⊕✗/✗✗/✗	Resistance to recombinant human erythropoietin (rHuEpo) is common in hemodialysis patients with functional iron deficiency, as is ascorbic acid deficiency. Adequate levels of available iron are necessary, but parenteral iron can produce iron overload with significant risks. Intravenous ascorbic acid improves anemia in iron-overloaded, EPO-hyporesponsive hemodialysis patients and facilitates elimination of iron from stores without reducing functional iron levels. Most but not all evidence is positive, and further research is warranted to further determine safety, efficacy, and indications.	Intravenous vitamin C may be appropriate in some patients resistant to EPO and at risk of iron overload. Close supervision and regular monitoring are warranted, particularly in dialysis patients.
Furosemide Loop diuretics ⊕/≈≈/☼	Ascorbic acid coadministration appears to significantly increase bioavailability of furosemide and enhance its diuretic and natriuretic effects. Several mechanisms are involved, with reduced gastric first-pass metabolism of furosemide the most important influence. Furosemide acutely increases urinary excretion of oxalic acid and vitamin C in individuals with chronic renal failure and may protect uremic patients against accumulation of oxalic acid. Limited evidence indicates absence of adverse effects and suggests further research warranted.	Coadminister vitamin C, as well as B vitamins, to optimize therapeutic effects and prevent depletion. Monitor for depletion of vitamins C and B_6, especially with renal failure and dialysis.
HMG-CoA reductase inhibitors (statins) ✗/✗✗/⊕✗/⊕	Relationship of statin drugs to oxidative stress is unclear and of potentially major significance as an adverse effect. Concomitant vitamin C may improve some lipid parameters (particularly LDL and triglycerides), promote glutathione, protect and regenerate vitamin E, and inhibit lipid peroxidation, all of which may contribute to reducing cardiovascular risk. However, the interaction between statins and antioxidants is controversial, and evidence suggests potential impairment of HDL-ogenic effects of niacin by antioxidants. Well-designed long-term trials are necessary to conclusively clarify mixed findings.	Consider coadministration of multiple antioxidants, including ascorbic acid, as well as fish oil and coenzyme Q10, to reduce adverse effects of statins and enhance therapeutic outcomes. Avoid combination in some cases. Monitor drug levels and liver enzymes regularly.
Indinavir Protease inhibitors ◈◈/◈◈◈	Concomitant high-dose ascorbic acid can reduce steady-state plasma concentrations of indinavir. However, while findings suggest possibility of subtherapeutic concentrations, limited evidence has not confirmed clinical significance. Further research needed, especially given high rate of self-medication among patient population.	Review inventory of nutrient and herb intake and caution against unsupervised intake of vitamin C and other agents in pharmacological doses. If nutrients indicated, monitor drug levels.
Lansoprazole-amoxicillin-metronidazole (LAM) triple therapy ⊕⊕/⊕✗/✗✗	Ascorbic acid secretion in the stomach is impaired with increased occurrence of *Helicobacter pylori*. LAM triple therapy enhances gastric vitamin C levels and recovery from gastritis, but eradication of *H. pylori* is not enhanced and may be impaired by simultaneous administration of vitamin C (and E). Evidence limited and research warranted.	Prudence suggests that patients be advised to avoid concomitant high-dose vitamin C during LAM triple therapy. Otherwise, advise diet rich in vitamin C in preventing gastric disease or reducing effects of *H. pylori* infection.
Levodopa, carbidopa Antiparkinsonian medications ⊕⊕/☼/◈≈≈/⊕✗/✗✗	Oxidative stress may contribute to Parkinson's disease and may be aggravated by levodopa monotherapy. Dopamine agonists and vitamin C both exert neuroprotective effects through antioxidant mechanisms, thus slowing neuron degeneration in the substantia nigra and preventing levodopa-induced neurotoxicity. Concomitant ascorbic acid can improve levodopa absorption, particularly in elderly patients, and possibly enable reduction of levodopa dosage without diminishing its effectiveness. Coadministration with levodopa-carbidopa can enhance functionality and symptom reduction in some but not all individuals. High-dose vitamin C contraindicated in certain patients, who may experience an exacerbation of dyskinesia; pretreatment screening is critical.	Administration of vitamin C (and E) may slow disease progression in Parkinson's patients. Coadministration of moderate-dose ascorbic acid (and B_6 and coenzyme Q10) with levodopa-carbidopa may be beneficial but needs to be gradually introduced, closely supervised, and regularly monitored.
Methotrexate ☼	Minimal case report data suggest that vitamin C might mitigate adverse effects associated with methotrexate therapy, particularly nausea. The particular case involved multiple medications, but signs of adverse effects or decreased drug efficacy from 1-3 g ascorbic acid were absent. Limited character of available evidence suggests caution in extrapolating to broader clinical implications. Use of antioxidants during chemotherapy is generally contraindicated outside context of medical care by trained and experienced clinicians.	Consider coadministration of vitamin C in moderate to high dose to alleviate nausea from methotrexate. However, caution, structured protocols, and close monitoring required during chemotherapy.
Nitroglycerin Nitrates ☼	Coadministration of vitamin C during nitrate therapy may prevent or reduce development of tolerance, at least in part, by mitigating free-radical formation. In particular, stabilization of mitochondrial aldehyde dehydrogenase involved in	Oral vitamin C may be used to prevent onset of nitrate tolerance, but intravenous ascorbic acid may be indicated in acute situations.

Continued

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
	bioconversion of organic nitrates by ascorbic acid may also contribute to reduction of tolerance. Further research warranted, especially toward establishing potent predictors of risk and efficacy.	Requires close supervision and regular monitoring by experienced clinicians.
Oral contraceptives (OCs) ≈≈≈/✗	Oral contraceptives may cause increased ascorbic acid turnover in tissues and reduce plasma, leukocyte, and platelet ascorbic acid levels. Conversely, high-dose ascorbic acid may impair conversion of ethinyl estradiol to its sulfates and elevate plasma levels of ethinyl estradiol although without interfering with ethinyl estradiol pharmacokinetics. Unqualified case reports of contraceptive failure or breakthrough bleeding following vitamin C use have not been confirmed by research. Evidence generally limited with inconsistencies and qualifications although findings generally suggest minimal adverse effect of either agent upon the other. Further research through well-designed trials warranted.	Monitor for adverse effects of oral contraceptives especially in women with compromised nutritional status. Consider coadministration of vitamins C, B_{12} and B_6, as well as folate and magnesium, in women demonstrating or at risk of adverse effects from exogenous estrogens.
Propranolol Beta-1-adrenoceptor antagonists ✗✗	Vitamin C may decrease the absorption and first-pass metabolism of propranolol, but this interaction appears to be of minimal clinical significance.	Separate oral intake of vitamin C if indicated during beta-blocker therapy. Monitor.
Tetracycline antibiotics ⊕⊕⊕/☼/≈≈≈	Concomitant intake of vitamin C can enhance bioavailability and elevate blood levels of tetracycline. It may also protect against adverse effect of tetracyclines, including dental and oral discoloration and hepatic and renal toxicity. Chronic tetracycline may reduce blood levels of and interfere with the activity of ascorbic acid, particularly in compromised individuals. Preliminary data promising and consistent but limited; further research is warranted.	Consider concomitant vitamin C with long-term tetracycline therapy to enhance therapeutic effects, reduce adverse effects, and prevent depletion, especially with compromised nutritional status.

NUTRIENT DESCRIPTION

Chemistry and Forms

The generic term *vitamin* C is used to describe the various compounds that exhibit the biological activity of ascorbic acid. Albert Szent-Györgyi first isolated ascorbic acid in 1928 from porcine adrenal glands. Originally called "hexuronic acid," *ascorbic acid* (Latin *a*, "not"; *scorbutus*, "scurvy") became the official nomenclature in 1933 after the correct structural formula was determined and it was successfully synthesized.

In nature, vitamin C appears in both its reduced form (L-ascorbic acid) and its oxidized form (L-dehydroascorbic acid), which interconvert in a reversible equilibrium. L-Ascorbic acid is the most active form, but both possess antiscorbutic activity. Vitamin C is water soluble and easily oxidized in solution and with heat.

Physiology and Function

Unlike many species that are able to synthesize vitamin C, humans require intake as a nutrient. Vitamin C is readily absorbed, predominantly in the distal portion of the small intestine (jejunum) and to a lesser degree in the mouth, stomach and proximal small intestine, through active transport mechanisms as well as passive diffusion. The pharmacokinetic profile of vitamin C is significant for decreased nonlinear absorption and increased nonlinear elimination with increasing oral doses. Intake of 400 mg per day (or 75 mg/dL) is required to saturate serum. Thus, although 70% to 90% of the dietary intake is absorbed, absorption falls to 50% with a dose of 1.5 grams (g). Once maximum serum level (> 1.4 mg/dL) has been attained, intake of greater than 400 mg/day results in increased tissue levels of vitamin C. It is transported in the free form with higher concentrations in leukocytes and platelets than red blood cells (RBCs) and plasma. RBCs reach saturation with 60 mg/day. Once in circulation, vitamin C is readily taken up and concentrated in a wide range of body tissues, with the adrenal glands containing the highest concentration, and other glandular tissues (e.g., pituitary, thymus, corpus luteum) also holding relatively higher concentrations. Whole-body stores are typically about 1.5 g. Vitamin C crosses the placenta and is excreted in breast milk. It is primarily eliminated through urine, but only a small proportion is excreted unchanged (unless plasma concentration > 1.4 mg/dL).

Vitamin C plays a central role in the biosynthesis and function of many key physiological substances. Given its high concentration in the adrenals (50 times that of serum), it is not surprising that vitamin C is required for the synthesis of adrenaline/epinephrine, noradrenaline/norepinephrine, cortisol, and histamine, all of which are involved in stress response. Moreover, adrenocorticotropic hormone (ACTH) stimulation induces significant loss of ascorbic acid from the adrenal cortex as part of glucocorticoid mobilization. Vitamin C is necessary for the synthesis of carnitine and thus essential to metabolism of fat as an energy source. It is also essential in the metabolism of folic acid, histamine, phenylalanine, tryptophan, and tyrosine and the optimal activity of several enzymes, specifically enabling the conversion of folacin to tetrahydrofolic acid, dopamine to epinephrine, and tryptophan to 5-hydroxytryptophan and eventually 5-hydroxytryptamine (serotonin). Vitamin C also enhances the bioavailability of iron, as well as aiding the reduction of ferric iron to ferrous iron and limiting the degradation of ferritin to hemosiderin.

Vitamin C is a powerful protective agent within the antioxidant, detoxification, and immune systems. Its activity as an antioxidant *par excellence* is well established and widely recognized. As a water-soluble substance with universal access to cells throughout the body, vitamin C acts as a powerful reducing agent in its own right, neutralizing free radicals by donating hydrogen atoms from its two hydroxyl (OH) positions. Furthermore, it functions synergistically with other antioxidants, particularly glutathione, the other major hydrophilic antioxidant, and vitamin E, a major lipophilic antioxidant,

which it can regenerate. Moreover, unlike other antioxidants that exhibit the potential of converting to pro-oxidant activity under conditions of high oxidative stress (or during in vitro experiments involving free metal ions), evidence from well-designed and physiologically relevant research is lacking to substantiate suggestions that oral vitamin C intake promotes oxidative damage in humans under physiological conditions.[1] Vitamin C protects cholesterol from oxidative damage by free radicals, lowers elevated low-density lipoprotein (LDL) cholesterol, and increases high-density lipoprotein (HDL) cholesterol. It decreases total cholesterol by facilitating the formation of bile, aiding cholesterol degradation/metabolism, and participating in its conversion to bile acids for excretion. It also decreases levels of lipoprotein(a) or Lp(a), which forms atherosclerotic plaques and helps dissolve such plaques, by reacting with insoluble calcium-phospholipid-cholesterol plaque to form soluble sodium-phospholipid-cholesterol and calcium ascorbate; it may also reverse dysfunction of endothelial cells lining the blood vessels.

Vitamin C is essential for the optimal activity of many important detoxification systems, particularly the hepatic cytochrome P450 (CYP450) mixed-function oxidase system and other enzymes responsible for metabolizing toxic substances, including heavy metals (e.g., mercury, lead, arsenic, cadmium, nickel) and many pharmaceuticals. Vitamin C inhibits hyaluronidase (the enzyme that degrades hyaluronic acid, a high-molecular-weight compound that functions as an intercellular matrix) and prevents formation of nitrosamines, carcinogenic compounds formed from dietary nitrate/nitrite compounds in the digestive tract. The numerous and profound roles of vitamin C in facilitating and regulating immune function include increasing levels of macrophage activity, lymphocyte production (neutrophils, lymphocytes, natural killer cells), and antibodies (IgA, IgG, IgM). It also elevates interferon production, modulates prostaglandin synthesis, and exerts antihistamine effects.

The activity of vitamin C is fundamental to the structural integrity, strength, and elasticity of the human body through its central role in the synthesis of collagen and elastin. These organic materials are essential to the formation, activity, and maintenance of skin, tendons, cartilage, muscles, intercellular connective tissue matrix, blood vessels, bone matrix, and tooth dentin. Specifically, the hydroxylysine cross-links in collagen require the activity of prolylhydroxylase and lysyl hydroxylase, enzymes that hydroxylate lysine and proline, and for which ascorbic acid acts as a reducing agent and coenzyme. Overall, collagen comprises 25% to 30% of total body protein, making it the most abundant protein in the body. Thus, vitamin C and its allied nutrients inherently play an important role in the healing and rebuilding of damaged tissues, such as strains, sprains, burns, scars, and fractures.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Vitamin C surpasses almost every other nutrient in the range of claims made for its use in promoting health and treating disease and in the popularity of its use as a supplement. Nevertheless, after more than half a century of controversy, evidence from controlled clinical trials and epidemiological studies remains limited and often speculative. Many groups within the general population, such as children, the elderly, and smokers, exhibit significant risk of vitamin C deficiency due to inadequate and inconsistent intake of vitamin C–rich foods and depletion due to medications and stressors. Nevertheless, observational studies largely indicate that populations with a higher dietary intake of vitamin C exhibit a lower incidence of cataracts, macular degeneration, cardiovascular disease, osteoarthritis, and some cancers.

Assertions of vitamin C's efficacy in the prevention of the common cold and cancer, in particular, have been focal points in a contentious and often unsubstantiated war of words, citations, and incongruous sets of assumptions, methods, and goals among divergent schools of medicine. For example, evidence for the protective effects of vitamin C against cancer is mixed, depending on study design, size and duration, nutrient source, dose, mode of administration, and the form of cancer involved, with cancers of the mouth, throat and vocal chords, lungs, esophagus, stomach, colon-rectum, and breast demonstrating inverse correlations, broadly or in select populations, in at least some studies. The application of "megadose" vitamin C as part of nutritional therapies in cancer care is even more controversial, and substantive dialogue between advocates and critics has rarely produced meaningful data or mutually satisfactory research. Review of numerous studies indicates beneficial effects of regular vitamin C, at moderate to high doses, in modestly reducing the duration of the common cold and respiratory infections and possibly the severity of symptoms. Research findings are more mixed regarding reductions in the frequency of infection. The weight of evidence in research within conventional medicine suggests a lack of benefit from long-term daily supplementation in preventing colds, except in individuals with low dietary intake, marathon athletes, or other populations with unusual circumstances.

Nevertheless, issues such as dosing strategies and delivery techniques, possible differences in physiological potency of supplemental forms from different sources, and concomitant nutrient synergies continue to separate the divergent therapeutic approaches. For example, in conventional discourse (and most human trials) a daily dose of 200 mg orally is often termed as "megadose vitamin C," and 2000 mg is considered a tolerable daily upper limit. However, among physicians specializing in nutritional therapeutics, such descriptors would be reserved for doses starting at 4 g (4000 mg) daily, and therapeutic intervention can involve intravenous (IV) administration. Consequently, the parties in this long-standing debate too often operate from such divergent views of clinical application, research methodology, and outcomes interpretation, so fundamental questions often go unanswered, the most meaningful issues remain go unresolved, and opportunities for effective collaboration can be lost.

Although findings from well-designed and adequately powered clinical trials have rarely attained the dramatic level of benefit asserted by pioneers and proponents, clinicians experienced in nutritional therapeutics have regularly been able to offer substantive critiques of conventional research methodology and suggest limited relevance of many trials to actual clinical application. As with nutritional research to this point in many areas, mixed findings may result more from variations in intervention (forms used, dose levels, methods of administration), trial characteristics (duration, patient populations, methods of assessing outcomes), and other variables than from the actual effects of the "vitamin C." Here the issues of dietary versus "supplemental" sources, as well as the multitude of supplemental forms, constitute fundamental factors in parsing evidence and extrapolating research findings. Overall, the use of oral doses may be appropriate for maintaining or restoring tissue levels, whereas IV administration of pharmacological doses is significantly more effective at obtaining greatly elevated plasma levels for short periods. Likewise, the benefits

of multiple interdependent and synergistic nutrients in food sources and many prescribing strategies using nutrients as cotherapies render distinguishing the effects of any single component virtually impossible and contrasts sharply with the more decontextualized, single-agent investigational methodology modeled on studies designed for pharmacological interventions and pathological conditions. Meaningful and enduring conclusions and an operative consensus within the broader medical community will require development of an expansive set of in-depth research from controlled clinical trials integrating insights from the full range of therapeutic perspectives.

Historical/Ethnomedicine Precedent

The discovery of scurvy prevention through citrus intake among British sailors resulted from what is generally considered the first example of a controlled experiment comparing results in two populations administered different diets. It implicitly revealed a connection between the diets of disparate cultures and their respective ecological settings and traditional diets and the impact of their deficits on human health and disease.

Possible Uses

Acute anterior uveitis, aging or sun-damaged skin, alcohol withdrawal, allergies, anti-inflammatory, asthma, atherosclerosis, autism, bedsores, bronchitis, bruising (easy, excessive), cancer (risk reduction), cancer treatment, candidiasis, capillary fragility, cataract, cervical dysplasia, chronic obstructive pulmonary disease (COPD), common cold, Crohn's disease, dermatitis, diabetes mellitus, dysbiosis, eczema, fatigue, gallbladder disease, gallstone prevention, gastritis, gingivitis, glaucoma, gout, hay fever, heart disease prevention, heavy metal detoxification, hepatitis, *Helicobacter pylori* infection, herpes simplex infection, herpes zoster infection, human immunodeficiency virus and acquired immunodeficiency syndrome (HIV/AIDS) support, hives, hypercholesterolemia, hypertension, hypertriglyceridemia, hypoglycemia, immune function enhancement, influenza, insomnia, intervertebral disc inflammation, iron deficiency anemia, low back pain, macular degeneration, male infertility (sperm agglutination, low sperm count), menopausal symptoms, menorrhagia, mitral valve prolapse, multiple sclerosis, muscle soreness recovery (postexercise), nausea of pregnancy, nitrate tolerance, oral premalignant lesions (risk reduction), osteoarthritis, otitis media (recurrent), Parkinson's disease, peptic ulcers, periodontal disease, peripheral vascular disease, photosensitivity, platelet adhesiveness, postherpetic neuralgia, preeclampsia (prevention), premature placental rupture, reflex sympathetic dystrophy (RSD) prevention, retinopathy, rheumatoid arthritis, schizophrenia, scurvy, sinusitis, skin ulcers, sports injuries, stress, sunburn (prevention), tardive dyskinesia, urinary tract infection, vascular dementia prevention, viral or bacterial infections, vitiligo, wound healing.

Deficiency Symptoms

Scurvy is the fundamental and defining picture of severe vitamin C deficiency and its description as the first identified nutritional deficiency disease constituted a landmark development in nutritional medicine. Frank scurvy is rare in the United States (U.S.) and Europe, but subclinical deficiencies are common. Symptoms of advanced vitamin C deficiency derive primarily from defective collagen synthesis and degenerative changes in capillaries, bone, and connective tissue, and include listlessness, fatigue, weakness, fever, shortness of breath, anorexia, erupted teeth with bleeding gums, ecchymoses, hemorrhage, anemia, edema, hypotension, convulsions, personality changes, hypertrophy of the cornea, icterus, perifollicular hyperkeratotic papules, dry skin, muscle cramps, aching bones, joints, and muscles, and secondary infections. Scurvy, uncorrected, is eventually fatal. Children can experience abnormal development of bones, teeth, and blood vessels and disturbances of growth. Capillary fragility, bleeding gums, easy bruising, poor wound healing, diminished antioxidant protection, increased susceptibility to infection, and fatigue are among the indicators of possible subclinical vitamin C deficiency.

Smokers are foremost among groups at risk of vitamin C deficiency, but the elderly, institutionalized persons, hospital patients, and diabetics are also highly susceptible. The Third National Health and Nutrition Examination Survey also identified those who did not use supplements and non-Hispanic black males as having elevated risks of vitamin C deficiency and depletion in the U.S.[2] Other groups characterized by specific metabolic stresses may need greater levels of vitamin C intake for proper physical activity and protective functions, including individuals with high alcohol intake, those with increased oxidative stress (e.g., exposure to chemicals, heavy metals, radiation), those in life phases of rapid growth (pregnancy, lactation, childhood, adolescence), and individuals with chronic illnesses (e.g., rheumatoid arthritis, diabetes, hyperthyroidism, chronic kidney failure). As discussed later, numerous medications can deplete vitamin C or interfere with its normal activities. Increased risk of developing cataracts and heart disease can result from degenerative processes associated with chronic vitamin C deficiency.

Other than humans and other primates (specifically gorillas, chimpanzees, and monkeys), guinea pigs and a rare species of bat are the only mammals that lack the ability to synthesize ascorbic acid from glucose.

Dietary Sources

Public education is necessary to correct the widely held misconception, founded more in marketing and advertising than in nutritional science, that fruits, especially citrus, are exceptionally rich sources of vitamin C. In fact, vegetables are richer dietary sources. Vitamin C can be lost through oxidation during storage and cooking, and boiling can cause leaching of the nutrient into the water (unless recovered by use, such as in gravy or soup).

Almost all fresh vegetables and fruits are potential sources of vitamin C. Foods particularly rich in vitamin C include broccoli, cauliflower, red bell peppers, red chili peppers, black currants, Brussels sprouts, cantaloupe, kale, parsley, turnip greens, collard, rose hips, citrus fruits, strawberries, apples, persimmons, papaya, guava, acerola cherries, potatoes, cabbage, tomatoes, and green bell peppers.

Nutrient Preparations Available

Vitamin C is present in most multivitamin preparations. Intravenous ascorbate solutions (sodium ascorbate, or ascorbic acid buffered to a pH > 5.5) are only administered by drip; IV push is contraindicated because of venous irritation. Osmalality of IV ascorbate solutions up to 1200 mOsm/L are well tolerated if the patient can take adequate fluids by mouth.

Scientific evidence is lacking to demonstrate superior bioavailability of any single form of orally administered vitamin C (L-ascorbic acid) compared with any other form. Although vitamin C from naturally occurring sources is favored by advocates of vitamin C therapy, naturally derived and synthesized forms of L-ascorbic acid are chemically identical, and limited human research has thus far demonstrated no significant differences in their respective biological activities or bioavailability, using standard assay methods and parameters of physiological effect. When formulated as a mineral salt, ascorbic acid is buffered (i.e., less acidic) and thus theoretically less irritating than simple ascorbic acid to the gastrointestinal (GI) tract. A wide range of mineral ascorbates are available, with sodium ascorbate (131 mg sodium per 1000 mg ascorbic acid) and calcium ascorbate (114 mg calcium per 1000 mg ascorbic acid) being the most common. The addition of small amounts of dehydroascorbate (oxidized ascorbic acid), calcium threonate, and trace levels of xylonate and lyxonate, all metabolites of vitamin C, to a base of calcium ascorbate, marketed as Ester-C, is purported to provide for enhanced bioavailability, but supportive evidence is lacking, although Ester-C does appear to be "much better tolerated" than "regular ascorbic acid," as indicated by "fewer epigastric adverse effects."[3] Similarly, although bioflavonoids and vitamin C often occur together in many fruits and vegetables, claims that combining them in supplements provides superior activity have yet to be substantiated. Vitamin C is normally water soluble, but a fat-soluble form, known as *ascorbyl palmitate*, has been synthesized for use in topical applications by esterifying vitamin C to palmitic acid, a saturated fatty acid; an oral form would be unlikely to escape breakdown through hydrolyzation before being absorbed in the digestive tract. Erythorbic acid is an isomer of ascorbic acid but may lack the primary antiscorbutic activity of ascorbic acid; it is used in the U.S. as a food additive, but not as a nutritional supplement.

Based on the finding that some tumors accumulate high levels of vitamin C, concern has been raised that vitamin C might make cancer treatment less effective.[4] However, there is virtually no evidence from clinical trials that vitamin C interferes with any type of cancer therapy. In contrast, multiple animal and clinical studies suggest that vitamin C may enhance cancer therapy, possibly by acting as a pro-oxidant when accumulated in large intracellular stores by tumors, then exposed to chemotherapy or radiation.[5-7,7a] (See Chemotherapy for further discussion.)

The tissue levels of ascorbic acid concentration obtained through IV administration are significantly greater than those associated with oral intake. Intravenous administration of vitamin C at 18 g/day can produce plasma concentrations 25 times those resulting from oral administration of the same dose. Recent pharmacokinetics models indicates that with oral administration, even large frequent doses of vitamin C, will increase plasma concentrations only modestly, from 70 mmol/L to a maximum of 220 mmol/L, whereas IV administration increases concentrations as high as 14,000 mmol/L. Plasma concentrations of 1000 to 5000 mmol/L are selectively cytotoxic to tumor cells in vitro, and emerging evidence indicates that vitamin C at concentrations achieved only by IV administration may function as a prodrug for hydrogen peroxide (H_2O_2) delivery to tumor tissues.[8-15] Such observations may account for the inconsistent findings and divergent conclusions in studies using oral versus IV modes of delivery. Rigidly imposing a preconceived model of the beneficial or adverse effects of pro-oxidant effects of nutrients is not likely to lead to clinically useful conclusions.

Dosage Forms Available

Capsules, liposomal spray, powders, tablets, chewable tablets, effervescent tablets.

Source Materials for Nutrient Preparation

Commercial vitamin C is synthesized from glucose by two primary methods. The Reichstein process, developed in the 1930s, applies a single prefermentation, followed by a purely chemical route. The two-step fermentation process, introduced in China in the 1960s, replaces the later chemical stages with further fermentation. The yield from either process is approximately 60% ascorbic acid from the glucose feed, usually derived from corn.

Sago palm–derived ascorbic acid has been developed for individuals with putative corn sensitivity.

Camu camu *(Myrciaria dubia)*, a bioflavanoid-rich berry from the Amazon rain forest, is an innovative source of vitamin C emerging in the marketplace

Dosage Range

Adult

Dietary: Vitamin C intake of 10 mg per day can prevent scurvy. The U.S. recommended dietary allowance (RDA) for vitamin C, or the daily dose required to prevent deficiency disease, is 90 mg/day for men and 75 mg/day for women; it was recently revised upward from 60 mg daily and had been 45 mg until 1974. The new, higher RDA takes into account for the first time the vitamin's role as an antioxidant as well as protection from deficiency. A special RDA has been established for adult smokers: 125 mg/day for men and 110 mg/day for women; Ames[16] has recommended that smokers need to consume two to three times more vitamin C than nonsmokers. The mean dietary intakes of vitamin C for adults in the United Kingdom (U.K.) and Germany were 87 and 76 mg daily and 75 and 72 mg daily for adult men and women, respectively.[17,18] Among elderly men and women in the U.K., vitamin C intakes of 72 and 68 mg daily, respectively, have been reported.[19] The National Health and Nutrition Examination Survey found that the median consumption of vitamin C from foods during the years 1988 to 1991 was 73 and 84 mg daily for men and women in the U.S., respectively.[20] All these studies have demonstrated a wide variation in vitamin C intake, with 25% to 30% of the U.S. population consuming less than 2.5 servings of fruit and vegetables daily. Dietary intake levels in other areas, such as Latin America, Africa, and Asia, are typically lower. Based on a review of the scientific literature, the Linus Pauling Institute recommends "that the RDA for vitamin C should be 120 mg/day for optimum risk reduction of heart disease, stroke, and cancer in healthy individuals. Special populations, such as older adults and individuals with disease, may require substantially larger amounts of vitamin C to achieve optimum body levels and derive therapeutic benefits."[21] Consuming at least five servings of fruits and vegetables daily may provide about 200 mg of vitamin C.[22]

Supplemental/Maintenance:

60 to 1000 mg/day.

Optimal daily intake: 0.5 to 3 g/day, depending on the individual.

Some research suggests that blood levels reach saturation at an oral intake of approximately 200 mg daily in healthy individuals, and assuming tissues are saturated, any intake above that amount may be excreted. However, the Linus Pauling

Institute recommends a vitamin C intake of at least 400 mg daily; this amount has been found to fully saturate plasma and circulating cells with vitamin C in young, healthy nonsmokers.[12,22] Individual variability can alter the metabolic effects of supplemental vitamin C, including nutrigenomic response variability, body weight, depletion status, and degree of tissue saturation based on recent patterns of intake.

Pharmacological/Therapeutic:

- 300 to 1000 mg/day typical for adults treated for scurvy.
- 500 mg/day to 20 g/day reported in scientific literature.
- Up to 70 g/day used therapeutically and in research settings.

Dosing to bowel tolerance is typically applied clinically as a practical (as well as variable and evolving) parameter in therapeutic administration of vitamin C. The laxation effects of large oral doses of vitamin C are likely because of the osmotic effects of unabsorbed ascorbate. The common clinical observation that the bowel tolerance of vitamin C increases substantially during acute viral illnesses suggests that more ascorbate is absorbed from the GI tract during such episodes.

Toxic: Although toxicity is rare, the tolerable upper intake level (UL) established by the Food and Nutrition Board (FNB) of the Institute of Medicine for vitamin C in adults was set at 2000 mg. Notably, this advisory body established the "no adverse effect level" (NOAEL) for vitamin C arbitrarily out of necessity because they were mandated to do so, even though their review of the scientific literature failed to find any "solid data" to support a toxic dose for vitamin C.[23] As stated by Johnston[24] in 1999: "The available data indicate that very high intakes of vitamin C (2 to 4 grams per day) are well tolerated biologically in healthy mammalian systems. Currently, strong scientific evidence to define and defend a UL for vitamin C is not available." Thus, this level is based on the potential for discomfort from possible diarrhea and GI disturbances (i.e., temporary and easily reversible responses) rather than actual toxicity in most individuals and is derived from uncontrolled case reports.[23]

Pediatric (<18 years)

Dietary:

- Neonates to 6 months: 40 mg/day (AI, adequate intake)
- 6 to 12 months: 50 mg/day (AI)
- 1 to 3 years: 15 mg/day (RDA)
- 4 to 8 years: 25 mg/day (RDA)
- 9 to 13 years: 45 mg/day (RDA)
- Adolescents, 14 to 18 years: 65 mg for females; 75 mg for males (RDA)

Supplemental/Maintenance: Usually not recommended for children under 12 years of age.

Pharmacological/Therapeutic: The treatment of scurvy in children typically requires 100 to 300 mg per day orally in divided doses for 2 weeks. Otherwise, vitamin C is generally not administered in pharmacological doses to infants or children.

Toxic: UL levels (oral):

- 0 to 12 months: none established
- 1 to 3 years old: 400 mg/day
- 4 to 8 years old: 650 mg/day
- 9 to 13 years old: 1200 mg/day
- Adolescents, 14 to 18 years old, including pregnant or breast-feeding females: 1800 mg/day

Toxicity is rare.

Laboratory Values

Physicians usually do not test vitamin C status, except for rare occasions of suspected scurvy. Most methods of laboratory assessment are generally considered neither sensitive nor precise in determining functional deficiency or systemic depletion. Further, high intake of vitamin C can interfere with some of the more frequently used laboratory tests.

Assessment of deficiency or depletion status.

Leukocyte ascorbate:

- Normal range: not established.
- Levels less than 114 mmol/108 cells (buffy coat) indicate deficiency.

Leukocyte concentrations may provide a good index of tissue stores of vitamin C.

Plasma ascorbate:

- Normal range: not established.
- Levels less than 2.6 mg/L (15 μmol/L) may indicate deficiency, but consistency in standards is lacking.

Plasma levels indicate metabolic turnover status of vitamin C. However, "extreme individual variability" has been documented with an identical vitamin C repletion dose in different individuals producing different plasma ascorbate levels based on body weight, prior depletion, and prior repletion.[25]

Urinary ascorbate:

- Normal range: not established.
- Excretion of less than 10 mg/day indicates severe deficiency.

Urinary ascorbate is generally considered an insensitive index of status except in severe deficiency.

Ascorbate loading test: An oral dose of 0.5 to 2.0 g ascorbic acid is administered over 4 days, and then urinary ascorbate is measured; excretion of less than 60% of dose indicates depletion of tissue ascorbate.

Lingual ascorbic acid test (LAAT): In this physician-administered test, a drop (from 25-gauge needle) of blue dye (2,6-dichloroindophenol sodium salt solution) is put on the tip of the tongue. Vitamin C status is indicated by the time required for the dye to disappear. Less than 20 seconds indicates normal levels; 20 to 25 seconds, marginal levels; and longer than 25 seconds, depletion of vitamin C levels. This is a functional test of the oxidation-reduction (redox) status of saliva and tissue, which is influenced by ascorbate status, but not specific for it.

As a strong reducing agent, ascorbic acid (>1 g daily) can interfere with some diagnostic tests, particularly those based on redox reactions. Evidence for some of these effects is mixed.

False-negative results on stool occult blood (guaiac assay) have been attributed to "high-dose" vitamin C intake within preceding 48 to 72 hours. False-negative results on urine acetaminophen tests have also been reported.

Vitamin C intake may produce false increases in levels in these serum tests: bilirubin, carbamazepine, creatinine, aspartate transaminase (AST, glutamic-oxaloacetic transaminase [SGOT]), uric acid.

Vitamin C intake may produce false decreases in levels in these serum tests: lactate dehydrogenase (LDH), theophylline.

Inaccurate readings on urinary glucose tests have been observed, with false negatives using glucose oxidase and false positives using cupric sulfate as the reagent test. Vitamin C–induced interference with blood glucose tests has been reported in the scientific literature but disputed.

Several unqualified case reports from the 1970s suggested that high-dose vitamin C could lower prothrombin time (PT) and cause increased clotting. Vigilance is appropriate whenever employing anticoagulant therapy, but evidence is too weak and inconsistent to represent this potential effect as highly probable or predictable, as discussed later.

SAFETY PROFILE

Overview

Vitamin C is safe across a broad range of intakes for most adults, according to a review and editorial by a team of eminent nutritional researchers.[26] Scientific evidence is lacking to demonstrate that even very large amounts of vitamin C are toxic or exert adverse health effects. Regular intake of dose levels well above the RDAs has been common in large numbers of individuals for decades. Adverse effects have been lacking in individuals, including Linus Pauling, who have consumed 10 g or more daily for extended periods. Systemic toxicity is improbable in healthy individuals because the primary effects of excess intake are mainly caused by large amounts of unabsorbed ascorbic acid in the intestine and, as such, typically do not alter circulating levels, are easily excreted, and respond rapidly to a decrease in intake. Thus, the Linus Pauling Institute, Oregon State University, concluded "that there is currently no consistent and compelling data for serious adverse effects of vitamin C in humans, and a UL can therefore not be established."[21]

Nutrient Adverse Effects

General Adverse Effects

Gastrointestinal (GI) discomfort, abdominal bloating, flatulence, dysuria, increased urinary frequency, skin rashes, loose stools, and diarrhea, resulting from the osmotic effects of unabsorbed vitamin C in the intestine, constitute the primary adverse effects in most individuals. Although providing the basis for the UL in the U.S., these responses are all dose related, resolve rapidly with decreased intake, and present no serious risk. Tolerance typically develops over time with gradual increase in dose. Diarrhea usually occurs with doses of 6 to 10 g daily but has been reported to afflict some individuals after only a single 1-g dose. Lowering the dosage to the highest level that does not provoke diarrhea (i.e., to "bowel tolerance") is a common method of determining maximal dosage for therapeutic effect.

Adverse Effects Among Specific Populations

Because of the importance of excretion as a regulatory process, individuals with compromised renal function may experience impaired elimination, excess accumulation, and increased lithogenicity.

Individuals with inadequate levels of glucose-6-phosphate dehydrogenase (G6PD) are at increased risk of a potentially severe adverse reaction, including possible hemolysis, after intake of certain oxidizing substances, such as high doses of vitamin C, orally or intravenously, suggesting that ascorbate might function as a pro-oxidant under certain conditions.[27] Genetic or G6PD enzyme activity testing is appropriate, particularly when IV ascorbic acid administration is contemplated.

In the general (U.S.) population, researchers have found "no association between serum ascorbic acid level and prevalence of kidney stones in women or men."[28] Nevertheless, certain individuals may theoretically exhibit increased risk of calcium oxalate stones with high-dose vitamin C intake because of potentially increased oxalate levels.[29] Vitamin C (ascorbic acid) is metabolized to dehydroascorbic acid, which in turn is metabolized to oxalic acid. In general, individuals who consume large amounts of vitamin C have shown either no change or a decreased risk of kidney stone formation in large-scale observational studies.[28,30,31] However, one of every 400 individuals possesses a defect in oxalate metabolism, resulting in idiopathic hypercalciuria, that could put them at increased risk of stone formation due to elevated urinary oxalic acid levels when administered high dose vitamin C (4-10 g orally). In a trial investigating the effect of calcium citrate supplementation on urinary calcium oxalate saturation in female stone-formers, Levine et al.[32] and associates found that "calcium citrate supplementation did not increase the lithogenicity." However, 2 years later in a study of vitamin C pharmacokinetics in healthy volunteers, these researchers reported that some individuals can experience an elevation in urinary oxalate levels after consuming 1000 mg of vitamin C per day, even in the absence of a history of kidney stones.[11] Auer et al.[33] expressed concern in reporting a small trial in which they observed sharp increases in excretion of urinary oxalate and sudden onset of hematuria due to formation of kidney stones in a single male subject who had consumed "large doses of ascorbic acid" for 8 days. Notably, in the paper describing the trial as a whole, these same authors "concluded that ingestion of large doses of ascorbic acid does not affect the principal risk factors associated with calcium oxalate kidney stone formation."[34]

In an interesting line of research, several small trials and a decade of clinical experience have consistently demonstrated the efficacy of lemonade in improving urinary citrate levels and reducing the occurrence of hypocitraturic calcium nephrolithiasis, in a manner similar to that of potassium citrate.[35-37]

Oxalate formation is saturable, and most of the population is unlikely to experience this complication. Hoffer[38,39] and other senior vitamin C researchers consider this kidney stone risk as exaggerated and inadequately demonstrated, possibly an artifact resulting from failure to acidify urine samples during collection. Some physicians experienced in nutritional therapies suggest that this risk may be mitigated by vitamin C's tendency to bind calcium, causing it to be excreted in urine, and rendering it unavailable for forming calcium oxalate stones. Likewise, Ester-C may be less likely than other forms of vitamin C to cause this rise in oxalate. Research is lacking to validate either of these propositions conclusively. Vitamin B_6 decreases oxalate production and may mitigate this risk.[31] Thiamine can also inhibit oxalate formation, as can correction of magnesium deficiency.[40] Nevertheless, health care professionals treating individuals at risk are advised to exercise extra caution in administering doses greater than 300 mg/day on a regular basis and to consider measuring urinary oxalate levels before and after beginning ascorbate supplementation.

Pregnancy and Nursing

Vitamin C is not known to cause mutations or birth defects in healthy individuals.[23] However, in one randomized, placebo-controlled trial involving 722 pregnant women at risk for preeclampsia, researchers observed a slightly elevated incidence of small-for-gestational-age neonates among women administered vitamin C (1000 mg) and vitamin E (RRR alpha-tocopherol, 400 IU) versus placebo.[41] A larger trial would be necessary to determine if this is a statistically significant and etiological effect, or if these events occurred by chance.

Infants and Children

The risk of "rebound scurvy" has been reiterated in innumerable secondary sources for decades, even though substantive scientific evidence is lacking. Theoretically, rebound scurvy could potentially occur in infants if the mother takes megadoses of vitamin C during gestation. This assertion is largely based on one poorly controlled study done by Cochrane in 1965 involving two infants whose mothers who had

consumed 400 mg of supplemental vitamin C during pregnancy. The vitamin C was discontinued abruptly after the births. These infants were receiving formula, and it was presumed that the formula had adequate levels of vitamin C. However, there was no analysis of the vitamin C content in the formula, nor was any attention given to the storage, preparation, or administration of the formula.[42] Thus, considering the number of women who have taken vitamin C during pregnancy, this small study occurring more than 30 years ago, and no similar cases documented, the risk is likely to be extremely low, if existent at all. The FNB Panel on Dietary Antioxidants and Related Compounds concluded that vitamin C does not cause "rebound scurvy" in healthy individuals.[23]

Contraindications

Cystinuria.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Individuals with a history of hemosiderosis, hemochromatosis, or other forms of iron overload.

Individuals with a history of recurrent nephrolithiasis, especially oxalate stone-formers, should avoid daily doses of 1000 mg or more outside the context of close supervision by an appropriately trained and experienced health care professional.

Megadoses (>4 g/day) in individuals with a history of renal failure outside the context of supervision by an appropriately trained and experienced health care professional, particularly on initiation of intake or significant change in dose.

Pregnant women should avoid daily doses above 500 mg without close medical supervision.

Use of doses greater than 1000 mg/day is generally contraindicated during forms of chemotherapy and radiation in which free-radical formation is an intentional part of the therapeutic mechanism. As discussed later, vitamin C and other antioxidants should be administered only in the context of direct supervision and close monitoring because of their potential inhibition of oxidation.

Precautions and Warnings

Patients with renal impairment or on chronic hemodialysis. Doses of vitamin C should not exceed 100 to 200 mg daily in individuals with renal failure.

Caution and close supervision are appropriate in administering vitamin C to individuals diagnosed with sickle cell anemia, sideroblastic anemia, or thalassemia.

Patients preparing for major surgery, particularly those at increased risk of hemorrhage, should not exceed 400 mg daily in the week before the procedure except under the supervision of an experienced health care professional.[43]

Individuals with sensitivities to corn may react to commercially available forms of vitamin C because most are derived from corn. Ascorbates derived from sago palm have been produced for extremely corn-sensitive individuals.

Long-term intake of high doses of vitamin C may induce copper deficiency.

INTERACTIONS REVIEW

Strategic Considerations

Whether in cardiovascular health, immune function, oncology, or preventing the common cold, vitamin C, or perhaps more accurately "the view of vitamin C," may constitute the most contentious and misunderstood topic, and thus probably the greatest single test of scientific discovery and clinical pragmatism, in integrative therapeutics and patient self-care. For decades, vitamin C has been the subject of intense controversy in medicine, the virtual bogeyman of medicine's Cold War era, and with its central physiological roles and its pervasive therapeutic potential, it presents a central opportunity for transdisciplinary collaboration and the emerging model of integrative therapeutics. Leading scientists and experienced clinicians, and throngs of self-administering patients, have voiced strong support for the preventive and therapeutic value of ascorbic acid ever since it was taken up by Linus Pauling and the clinicians proposing "orthomolecular medicine." On the side of the status quo, researchers and the institutions of conventional medicine have consistently voiced skepticism, disinterest, and often disdain for the exuberance of what they have seen as overamplified extrapolations of questionable anecdote. Nevertheless, the paradigm and treatment protocols of the pioneers and their successors have rarely been studied or applied intact by the conventional researchers who have investigated vitamin C. Richards,[44] Segerstråle,[45] and others have described a systematic pattern of bias against vitamin C therapeutics, particularly in contrast to conventional agents such as 5-fluorouracil and interferon. Hemilä[46] has suggested that "Pauling's conclusions were dismissed because of the fundamental divergence with the traditional notion that the only purpose of vitamin C is to prevent scurvy and not because of experimental findings." He also cited the work of Goodwin and Tangum[47] as providing "several examples to support the conclusion that there has been systematic bias against the concept that vitamins might be beneficial in levels higher than the minimum required to avoid classic deficiency diseases."[46]

In the absence of a theoretically clear and clinically operative model of integrative medicine, a strident attitude and lack of respect on both sides have contributed to the absence of a substantive scientific debate, to the detriment of both scientific knowledge and patients. Fortunately, scientific knowledge of vitamin C has grown progressively, as has a deeper appreciation of nutritional therapies in general. Moreover, new "discoveries" have become possible with the greater openness in scientific research to incorporating the therapeutic models of natural medicine, and thus more accurately resembling its clinical practice. These changes within the broader world of medical practice, education, and research have opened the doorway for a more systematic and comprehensive study of vitamin C, its essential role in human health, possibilities for therapeutic application, and the operative considerations for beneficial and adverse interactions within a clinical context encompassing conventional pharmacology. Considering the widespread use of vitamin C by all sectors of the patient population, self-administered or prescribed by nonconventional health care professionals, the sparsity of substantive clinical research data is striking and the basis for any sweeping generalizations about benefits, dangers, or interactions woefully inadequate.

It is useful to divide the clinical investigation of vitamin C into its physiological (coenzyme and antioxidant) functions (up to intakes of 400 mg/day, at which point tissue levels become saturated) and its pharmacological dosage range (multigram doses orally, up to 100 g intravenously). Evidence suggests that high-dose, particularly parenteral, ascorbic acid functions as a redox potential–modulating agent rather than a vitamin or antioxidant. Confusion between these two distinct roles of ascorbic acid may be the source of conflicting data in this field.

Under certain conditions, ascorbic acid, whether from natural or synthetic sources, can interact with numerous

pharmacological agents, beneficially, adversely, or bimodally, depending on clinical management. In particular, through its antioxidant activity and influence on drug-metabolizing enzymes, vitamin C may amplify or mitigate adverse effects (sometimes intended effects) of numerous pharmacological agents or, in some cases, potentially impair the desired therapeutic activity of such agents. Here the issue of ascorbic acid coadministration with chemotherapy or statin drugs has been the most contentious. In both regards, theoretical concerns about the antioxidant or pro-oxidant effects of vitamin C in conjunction with conventional therapies have been based all too often on questionable assumptions and limited research. Many conclusions have been made absent substantive evidence from large, lengthy, and well-designed trials focusing on the specific proposed interactions involving vitamin C. Health care professionals of all schools of thought and therapeutic approaches share these concerns, but those experienced in their application in clinical settings regularly point out that most cited research is preliminary and of only limited similarity to actual clinical practice. The paramount need is for well-designed and adequately powered trials that will critically assess the therapeutic use of vitamin C in these clinical contexts; determine the frequency, character, and clinical significance of any substantive interactions; and offer guidelines for shaping the clinical adaptations necessary for ensuring safety and optimizing outcomes. Moreover, in such investigations, particular attention must focus the form, dosage, and mode of vitamin C administration, concomitant conditions and treatments, and individual pharmacogenomic, lifestyle, and personal history factors characterizing the subject population, so as to discern specific influential variables and customize therapeutic responses accordingly.

Distinguishing use of vitamin C as nutritional supplement and patient self-care practice from high-dose ascorbic acid administration, orally or intravenously, by trained and experienced health care professionals applying coherent multidisciplinary strategies constitutes a critical first step to any meaningful scientific dialogue and productive research agenda. For example, approaches such as alternating administration but avoiding simultaneous intake, as practiced in many integrative oncology clinics, and purposeful selection of IV or oral administration represent significant clarifications that could benefit research design. Thus, in most observed interactions, doses less than 1 g/day are generally much less likely to precipitate adverse interactions, particularly given adequate separation of intake when indicated. High versus low dosage levels and IV versus oral administration almost always need to be considered as distinct from each other.

Likewise, few conclusive judgments can be made (or even hypothesized) as to the efficacy or risks of vitamin C within oncological treatment programs until further research is conducted into the contentious but largely unexplored issue of whether vitamin C always acts as an antioxidant or whether and when it may shift to pro-oxidant activity, as well as the corollary questions as to under what certain conditions this might occur and how that might affect interactions, effects, and outcomes. Further, the question of whether vitamin C can and should be investigated as an isolated nutrient or as a component of a broader nutrient-based interventions needs to be recognized, addressed, and sorted, especially with regard to such key issues as the preventive and therapeutic use of antioxidants and the respective emphasis on dietary versus supplement versus pharmacological forms. The important concepts embodied in the work of Bruce Ames and his collaborators regarding the importance of nutrients to genetic stability and exemplified by the extended SU.VI.MAX study in France provide useful models for the further development of research methodology that can deliver clinically relevant findings.

A wide range of drugs and drug classes can cause adverse effects or induce harmful reactions by interfering with the normal physiological activities of vitamin C and depleting functional levels in diverse tissues. As with most patterns of nutrient depletion or physiological impairment, patient susceptibility to clinically significant adverse effects from drug-induced vitamin C depletion depends largely on the nutritional status, concomitant medical conditions, and drug intake and other patient-specific factors, as well as the dosage level and treatment duration of the medication(s) involved. In some situations, coadministration of vitamin C, usually with synergistic nutrients, may only be appropriate for individuals with compromised nutritional status resulting from diet, disease, genetics, or medications, and then primarily in relation to intensive or prolonged drug regimens. In other situations, where concomitant ascorbic acid presents no significant risk of adverse effects or interactions, routine prophylactic administration may be judicious.

NUTRIENT-DRUG INTERACTIONS

Acetaminophen

Acetaminophen (APAP, paracetamol; Tylenol); combination drugs: acetaminophen and codeine (Capital and Codeine; Phenaphen with Codeine; Tylenol with Codeine); acetaminophen and hydrocodone (Anexsia, Anodynos-DHC, Co-Gesic, Dolacet, DuoCet, Hydrocet, Hydrogesic, Hy-Phen, Lorcet 10/650, Lorcet-HD, Lorcet Plus, Lortab, Margesic H, Medipain 5, Norco, Stagesic, T-Gesic, Vicodin, Vicodin ES, Vicodin HP, Zydone); acetaminophen and oxycodone (Endocet, Percocet 2.5/325, Percocet 5/325, Percocet 7.5/500, Percocet 10/650, Roxicet 5/500, Roxilox, Tylox); acetaminophen and pentazocine (Talacen); acetaminophen and propoxyphene (Darvocet-N, Darvocet-N 100, Pronap-100, Propacet 100, Propoxacet-N, Wygesic); acetaminophen, butalbital and caffeine (Fioricet).

Effect and Mechanism of Action

Both acetaminophen and ascorbic acid are metabolized and excreted in part by conjugation to sulfate. Their competition for available sulfate in the body can inhibit the conjugation of acetaminophen with sulfate. This can significantly decrease the fraction of a dose of acetaminophen excreted as acetaminophen sulfate and increase the fraction excreted as acetaminophen glucuronide. Thus, by decreasing the excretion rate of acetaminophen sulfate, ascorbic acid can increase the apparent biological half-life of acetaminophen.[48] Such effects may

increase therapeutic activity but can also elevate risks associated with excess acetaminophen, particularly hepatotoxicity (caused by depletion of hepatic glutathione). However, esters of ascorbic acid, such as ascorbyl stearate or ascorbyl palmitate, may also be capable of reducing the reactive intermediate back to the parent compound, and thus hepatic ascorbate can provide enhanced protection against acetaminophen-induced hepatotoxicity, as indicated by reductions in biochemical markers of hepatotoxicity, such as serum transaminase and serum isocitrate dehydrogenase (SICD) activities. Furthermore, L-ascorbic acid esters appear to facilitate hepatic glutathione (GSH) regeneration after coadministration of a hepatotoxic dose of acetaminophen.[49,50]

Research

Acetaminophen remains one of the most common toxic exposures and causes significant morbidity and mortality. Acetaminophen-induced acute hepatic failure, usually by intentional overdose but sometimes inadvertent, represents a major risk in conventional medical practice.[51-53]

In a clinical experiment involving five healthy adult volunteers, Houston and Levy[48] administered an oral dose of ascorbic acid (3 g) 1.5 hours after an oral dose of 1 g acetaminophen. They observed a "rapid and pronounced decrease in the excretion rate of acetaminophen sulfate" with a "significant increase in the fractions of the dose of acetaminophen excreted as acetaminophen glucuronide" and a "decrease in the fraction excreted as acetaminophen sulfate." Thus, competitive inhibition of acetaminophen's conjugation with sulfate by the ascorbic acid produced an increase in the "apparent biological half-life of acetaminophen from 2.3 ± 0.2 (mean ± SD) to 3.1 ± 0.5 hr." Notably, concomitant administration of sodium sulfate prevented these effects; thus confirming the pivotal role of sulfate conjugation.

Mitra et al.[49] conducted two investigations exploring the effect of ascorbic acid esters on acetaminophen-induced hepatotoxicity in mice. In the first, they administered a hepatotoxic dose of acetaminophen alone and with ascorbyl stearate or ascorbyl palmitate at 600 mg/kg for each substance and observed that coadministration of the ascorbate esters with acetaminophen "prevented an increase in liver weight/body weight ratios and hepatic glutathione depletion . . . by reducing the reactive intermediate back to the parent compound." Further, the combined acetaminophen–ascorbyl stearate treatment demonstrated enhanced antipyretic effect, compared to acetaminophen alone or with ascorbyl palmitate, as evidenced in significantly greater reductions in rectal temperature at 15- to 30-minute postdosing periods. Subsequently, Mitra et al.[50] examined the effects of acetaminophen alone and with each of the same ascorbic acid esters on the activities of serum transaminases (glutamic-pyruvate transaminase [SGPT, ALT], glutamic-oxaloacetic transaminase [SGOT, AST]) and SICD. They observed significant reductions in serum transaminase and SICD activities in the animals treated with either acetaminophen–ascorbate ester combination, compared with acetaminophen-positive controls. Although oral coadministration of acetaminophen with ascorbate ester did not prevent the initial hepatic GSH depletion (15 minutes to 4 hours after dosing), they reported that hepatic GSH content began to rise in the animals treated with either acetaminophen–ascorbate ester combination at 4 hours and reached control values within 12 hours after dosing. Further, urinary mercapturate conjugates measured over a 60-minute postdosing period were significantly lower and plasma sulfobromophthalein (BSP) retention was approximately eight times higher in the animals treated with acetaminophen alone versus either acetaminophen–ascorbate ester combination. These findings indicate "maintenance of hepatic excretory functions" in the presence of ascorbyl stearate or ascorbyl palmitate and the "possible role of L-ascorbic acid esters in GSH regeneration."[50] Although limited in their extrapolation to humans, these studies using a rodent model provide potential value in understanding the mechanisms of vitamin C in mitigating the adverse effects of acetaminophen in hepatotoxicity.

Emerging research indicates that "profuse and dysregulated production of cytokines, growth factors, and/or other endogenous substances during viral/bacterial infections and inflammation states play a role in the development of drug-induced liver injury," particularly in relation to "administration of drugs or hepatotoxicity associated with administration of therapeutic doses of acetaminophen in some genetically predisposed subjects."[54] The relevance of therapeutic administration of vitamin C and nutrients with similar activity within a comprehensive and individualized strategic approach to inflammation and infection (and avoidance of hepatotoxicity) deserves further investigation.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The collective findings from these initial studies indicate a complex, and as-yet incompletely understood, relationship between acetaminophen and vitamin C. The potential for elevated circulating levels of acetaminophen in the presence of vitamin C suggests the opportunity for equivalent therapeutic effects with a lowered drug dose. Given the well-established toxicity of acetaminophen, such a potentially beneficial interaction deserves further exploration through well-designed, adequately powered clinical trials. However, this potential value is complicated by the significant likelihood of patients self-administering both agents during acute infections and is therefore worthy of frank inquiry and educational overtures. Although such effects are unlikely to constitute a major risk with short-term acetaminophen use for pain or fever in most individuals, acute acetaminophen toxicity in previously healthy individuals has been documented. Moreover, such risks are significantly greater in individuals with compromised hepatic or renal function, and any use of acetaminophen is contraindicated, with or apart from vitamin C, in such individuals except under the supervision of a medical professional.

Acetylsalicylic Acid (Aspirin) and Salsalate

Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine), ASA, codeine, butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab).

Effect and Mechanism of Action

Vitamin C has been shown to reduce gastric mucosal damage and gastric toxicity induced by ASA-generated reactive oxygen metabolites.[55,56] After ingestion, both aspirin and salsalate are rapidly converted to salicylic acid. Aspirin and salicylic acid can increase urinary excretion of vitamin C, lower leukocyte ascorbic acid levels (by 50%), and decrease its metabolic availability.[57-60]

The gastric mucosa is the largest depot of ascorbic acid in the human body, with ascorbic acid concentrations 25 times higher than in plasma.[61] Some data suggest that aspirin may protect endothelial cells from oxidant damage via the nitric oxide (NO)–cyclic guanosine monophosphate (cGMP) pathway.[62,63] However, gastric epithelial cells require vitamin C to translate inducible heme oxygenase (HO-1) mRNA "into active protein, which then may exert gastroprotection by its antioxidant and vasodilative properties. . . . Induction of HO-1 is considered to be an adaptive cellular mechanism in response to oxidative stress."[64] Thus, a significant body of data shows that the oxidative damage caused by aspirin can induce exfoliation of gastric epithelial cells, formation of gastric erosions, and GI hemorrhage. In particular, the gastric mucosa of individuals deficient in vitamin C (and possibly other, synergistic nutrients) might be less able to increase the rate of cell production and therefore susceptible to increased bleeding after aspirin ingestion.

Vitamins A, E, and C and bioflavonoids may enhance the "antiaggregative effect of aspirin, prolongate its activity, [and] increase hypocoaguloemia due to reduced releasing of thrombocytic factors 3 and 4 into plasma."[65]

Research

Russell, Goldberg, et al.[57,66] published two related studies in *The Lancet* in 1968 that examined the relationships between leukocyte ascorbic acid levels (L.A.A.) and GI hemorrhage in humans and aspirin and gastric mucosa in vitamin C–depleted guinea pigs. On measuring leukocyte-ascorbic acid levels in 60 patients with GI hemorrhage, they found that the mean value of 14.2 $\mu g/10^8$ white blood cells (WBCs) was "significantly lower than that found in a matched peptic ulcer control group (17.6) and in a healthy control group (23.7)." They determined that ascorbic acid levels were "significantly lower in patients in whom aspirin or alcohol might have precipitated bleeding than in those in whom no precipitating factor was present," and that "the association of low L.A.A. levels with aspirin or alcohol ingestion was present whatever the causation of haemorrhage." they concluded: "Subclinical scurvy may be an additional factor in maintaining haemorrhage initially precipitated by aspirin or alcohol, and poor dietary intake of vitamin C seems the most probable explanation for the low L.A.A. levels observed." This susceptibility to bleeding from acute gastric lesions (erosions) appears greater in elderly individuals.[67] In the animal experiment they observed:

> "Guineapigs on the scorbutogenic diet bled from the gastric mucosa significantly more often than those on a normal diet. The addition of aspirin to a scorbutogenic diet significantly increased the likelihood of gastric mucosal bleeding." These findings led them to conclude that aspirin "thus seems to precipitate gastric mucosal haemorrhage more readily when guineapigs are in a subclinical scorbutic condition." Thus, based on both studies they interpreted their results to "suggest that aspirin is more likely to cause significant gastric mucosal haemorrhage when subclinical scurvy is present."[66] In a subsequent letter, Croft[67] reviewed several studies regarding the impact of malnourishment on compromised gastric mucosa and aspirin-induced loss of epithelial cells and proposed that an "explanation of their findings could be that a low turnover of gastric epithelial cells renders the mucosa particularly susceptible to aspirin."

Sahud and Cohen[68] compared platelet and plasma levels of ascorbic acid and the effect of aspirin ingestion in 48 healthy individuals and 34 patients with rheumatoid arthritis. They observed that plasma ascorbic acid levels were "abnormally low in all rheumatoid subjects except those taking supplemental vitamin C." Moreover, looking at platelet levels of ascorbic acid, which more accurately reflect tissue stores than plasma levels, they found "significantly low platelet levels of ascorbic acid. . . only in those rheumatoid patients receiving high doses of aspirin—i.e., 12 or more tablets per day." Based on these findings, they concluded that "a high dosage of aspirin in patients with rheumatoid arthritis is associated with tissue ascorbic acid depletion" and recommended that "administration of supplemental ascorbic acid to rheumatoid patients receiving a high dosage of aspirin as primary therapy seems warranted."[68]

Loh et al.[58] examined the effect of aspirin on uptake of ascorbic acid into leukocytes in both in vitro and human studies. First, they compared the uptake of ascorbic acid into leukocytes incubated in a buffered medium of ascorbic acid with that in a medium also containing aspirin and observed that the aspirin completely inhibited absorption of the ascorbic acid. In normal adults, they observed a significant increase in plasma and leukocyte ascorbic acid during the 2 hours after administration of 500 mg ascorbic acid but found that simultaneous administration of 600 mg aspirin "further increased plasma ascorbic acid concentrations but completely arrested uptake of ascorbic acid into the leukocytes." Likewise, administration of ascorbic acid every 6 hours increased urinary excretion of ascorbic acid and produced a concomitant increase in leukocyte ascorbic acid. In contrast, the "simultaneous administration of aspirin with the ascorbic acid resulted in a further

significant increase in excretion of ascorbic acid and a simultaneous fall in leukocyte ascorbic acid." Further, administration of aspirin every 6 hours for 7 days "resulted in diminished plasma and leukocyte ascorbic acid concentrations within four days. Thereafter, reduced ascorbic acid levels just in excess of those associated with production of scorbutic symptoms were maintained." The authors concluded that "supplementary ascorbic acid should be administered to individuals receiving aspirin therapy."[58]

Not all researchers have demonstrated this adverse effect of aspirin on vitamin C levels; at least not in healthy populations. Johansson and Akesson[69] conducted a clinical trial in which healthy adults were given four different diets for 1 week: "low ascorbic acid diet, low ascorbic acid diet plus acetylsalicylic acid" (3 g/day), "high ascorbic acid diet" (1 g/day), and high ascorbic acid diet plus acetylsalicylic acid. They observed that "at low ascorbic acid intake, acetylsalicylic acid increased urinary ascorbic acid, but at high ascorbic acid intake, acetylsalicylic acid instead decreased urinary ascorbic acid." They hypothesized that the latter effect resulted from inhibited intestinal absorption of ascorbic acid, and the former effect from "decreased protein binding and tissue uptake of ascorbic acid caused by acetylsalicylic acid." Overall, they reported that in "no instance" did the acetylsalicylic acid affect plasma ascorbic acid levels.

In a double-blind, randomized, crossover study involving 14 healthy volunteers, McAlindon et al.[56] administered aspirin 900 mg twice daily and either placebo, vitamin C 1 g twice daily, allopurinol 100 mg twice daily, or sulphasalazine 1 g twice daily for 3 days. They demonstrated that aspirin induced gastric injury, as assessed endoscopically and by quantifying mucosal reactive oxygen metabolite release by measuring chemiluminescence, but reported that no drug reduced any parameter of gastric injury. However, they found that vitamin C reduced duodenal injury, as assessed by Lanza score.

In two studies involving healthy subjects, Dammann et al.[70] and Schulz et al.[61] investigated the effects of the interaction between aspirin and ascorbic acid on gastric mucosa and plasma ascorbic acid concentrations. In the first, a randomized, four-fold crossover study, they performed serial esophagogastro-duodenoscopy on 17 healthy subjects before and after each course of 4-day dosing and collected gastric aspirates to detect microbleeding. They observed that subjects administered the combination of buffered acetylsalicylic acid and ascorbic acid "yielded the lowest Lanza score, the lowest increase in the number of mucosal petechiae and the lowest increase in the amount of gastric microbleeding." In contrast, those subjects receiving "acetylsalicylic acid plus paracetamol plus caffeine showed the highest Lanza score of all treatments, and a considerably greater sum of petechiae in the oesophagus, stomach and duodenum compared with those receiving buffered acetylsalicylic acid plus ascorbic acid." The authors concluded that this "trial confirms that buffering of acetylsalicylic acid improves local gastric tolerability."[70] In a related prospective, randomized, double-blind, parallel-group study involving three groups of 15 subjects each, these researchers compared concentrations of ascorbic acid in "gastric mucosa, gastric juice, urine and plasma in healthy subjects under steady state and fasted conditions" after 6 days of ascorbic acid (0.48 g/day) with and without concomitant administration of acetylsalicylic acid (0.8 g/day). Treatments were switched without any washout, resulting in a 14-day study period overall. Initially, they found that ascorbic acid concentrations were highest in the gastric mucosa, followed by gastric juice, plasma, and urine. Subsequently, on day 7, ascorbic acid concentrations in gastric mucosa, plasma, and urine had increased to a statistically significant degree in those groups receiving ascorbic acid and decreased significantly in the group receiving aspirin only. During this period, differences in ascorbic acid concentrations in gastric juice, between the treatment groups, were not statistically significant. Thus, in healthy subjects, "clinically relevant doses" of aspirin reduced ascorbic acid concentrations in gastric mucosa "by about 10% within six days resulting from antioxidative defense mechanisms." The authors concluded by recommending, as beneficial, a "protective adjunct administration" of vitamin C, particularly in "patients with long-term ASA treatment or conditions with additional risks such as elderly subjects with unfavorable dietary conditions and impaired antioxidative protection."[61]

Animal experiments by Byshchevskil et al.[65] indicate that concomitant administration of aspirin with antioxidants, specifically, vitamins A, E, and C and bioflavonoids, "in balanced diet in doses adequate to therapeutic ones" may potentiate aspirin's antiaggregative effect. They recommended more research and suggested that "administration of [the] vitamin combination studied is likely to diminish thrombocyte aggregative activity to a level needed using lower aspirin doses." More recently, Fiebich et al.[71] reported "synergistic inhibitory effect of ascorbic acid and acetylsalicylic acid on prostaglandin E_2 release in primary rat microglia."

The effects of vitamin C on renal clearance of aspirin suggest another potential interaction from coadministration, although bimodal in its clinical implications. In a review on drug-nutrient interactions among elderly patients, Schumann[72] noted that "high doses of vitamin C" can further reduce renal clearance of acetylsalicylic acid and other acidic drugs among elderly patients, in whom renal clearance is often impaired. As suggested by the author, and concurrent with the findings of several studies previously discussed, this possible pattern of interaction indicates an influence of vitamin C on the risk of toxicity inherent to aspirin that is neither inherently adverse nor beneficial. Professional supervision and reasonable monitoring are warranted, with titration of aspirin dose being an advantageous possibility. Such situations can represent risks or opportunities, depending on the characteristics of the patient and the rationale for aspirin administration, and reiterate the preeminent need for inquiry about patient use of supplemental nutrients and comprehensive and coordinated clinical management of the intake of drugs and nutrients among geriatric patients, which is numerous and complex in most cases.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Aspirin and vitamin C may be the most frequently self-prescribed medicinal substances in modern culture, and as a result, many individuals forget that adverse effects are a possibility with any agent. Health care professionals treating patients regularly taking aspirin are advised to educate them regarding the inherent risks of aspirin intake, particularly damage to the GI mucosa and microhemorrhage. In this context, it may also be prudent to suggest the potential protective value of supplementing with 200 to 500 mg vitamin C per day, as typically found in multivitamins. Although not conclusive, the body of available evidence indicates that vitamin C may moderate several of the adverse effects associated with aspirin intake and may provide some synergistic influence. Further, the populations more likely to use aspirin regularly are also more likely to be elderly, to have aspirin-induced gastric mucosal damage and bleeding, and to be on a nutrient-compromised diet, all of which increase the adverse effects of aspirin on vitamin C

status and general health. Professional supervision and periodic monitoring are warranted in such patients, as well as in those with compromised renal function, to avoid adverse effects of aspirin and any potential added risk that might theoretically derive from coadministration of vitamin C. Although not yet the direct subject of scientific research, the known supportive influence of vitamin C on absorption of nonheme iron might be of benefit in countering the tendency to anemia in those using aspirin on a regular basis. Lastly, chronic use of aspirin, other than as cardiovascular prophylaxis, suggests the need for a more fundamental therapeutic strategy aimed at analyzing and resolving the causes of pain and inflammation.

Antihypertensive Medications (Generally)

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability: **3. Possible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

The antioxidant activity of vitamin C may play a protective role against the increased production of reactive oxygen species associated with essential hypertension.[73] High-dose intra-arterial ascorbic acid levels may ameliorate endothelial dysfunction in individuals with hypertension.[74]

Research

In a small, randomized, double-blind, placebo-controlled trial, Duffy et al.[75] investigated the effect of ascorbic acid treatment on blood pressure in 45 patients with hypertension who continued conventional antihypertensive medications. Systolic, diastolic, and mean blood pressures in the treatment and placebo groups were similar at baseline and after acute treatment. They observed that 1 month of ascorbic acid treatment (500 mg/day) significantly decreased systolic blood pressure, in contrast to placebo, which had no effect. Likewise, after 1 month, ascorbic acid decreased mean blood pressure from 110 (12) to 100 (8) mm Hg, an effect significantly different from placebo. However, whereas 1 month of ascorbic acid decreased diastolic blood pressure, this response was not significant compared with placebo. Based on these findings, the researchers concluded that "the present study suggests that 500 mg of ascorbic acid daily is useful for blood pressure control in patients with hypertension" and suggested continued research with larger and longer clinical trials. They also noted: "Epidemiological studies show that dietary intake of ascorbic acid correlate inversely with hypertension and its clinical sequelae."[75]

Another study on the progression of hypertension produced potentially important findings related to vitamin C usage, but not directly related to an interaction between vitamin C and conventional antihypertensive drugs. Kim et al.[76] conducted a double-blind, randomized, controlled trial comparing the effects of 50 or 500 mg daily for 5 years on blood pressure in 224 Japanese subjects in a region with high gastric cancer and stroke mortality levels. Before supplementation, neither systolic nor diastolic blood pressure was significantly related with the serum vitamin C concentration. They found that vitamin C administration failed to produce any significant decrease in systolic or diastolic blood pressure. After 5 years, systolic blood pressure significantly increased in groups, regardless of vitamin C dose, compared with baseline, with the increase in low-dose and moderate-dose groups quite similar. Notably, study subjects were slightly less likely to smoke than the general population, but had all been serologically diagnosed with atrophic gastritis.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Further research into the potential interaction between antihypertensive medications and vitamin C is warranted. Pending substantive findings, physicians might find it prudent to prescribe vitamin C, at a modest dose level, to patients undergoing treatment for hypertension. Proper monitoring at home and during periodic examinations is appropriate, but no substantive research data indicate a significant risk for such individuals with vitamin C administration over an extended period. The importance of a diet emphasizing vegetables and fruits (i.e., rich in nutrients such as vitamin C) is fundamental and should be vigorously conveyed to patients.[77]

Chemotherapy and Radiotherapy

Including cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox), docetaxel (Taxotere), doxorubicin (Adriamycin, Rubex), etoposide (Eposin, Etophos, VePesid, VP-16), fluorouracil (5-FU; Adrucil, Efudex, Efudix, Fluoroplex), gemcitabine (Gemzar), rinotecan (camptothecin-11, CPT-11; Campto, Camptosar), methotrexate (Folex, Maxtrex, Rheumatrex), paclitaxel (Paxene, Taxol).

Effect and Mechanism of Action

Oxygen radicals can act as highly toxic stressors contributing to oncogenesis and other pathological processes. Higher intake of vitamin C and related nutrients through dietary sources is generally associated with reduced risk for many forms of cancer. In particular, vitamin C is known for direct activity as a free-radical scavenger, its central role in supporting intracellular glutathione (GSH) stores, and its synergistic relationship with other antioxidant nutrients and *N*-acetylcysteine (NAC).[78] Emerging research indicates that pharmacological ascorbic acid concentrations, as attainable through IV administration, selectively kill cancer cells in vitro and act as a prodrug to deliver hydrogen peroxide to tissues.[14]

In most cases the interaction between vitamin C and antineoplastic agents may be characterized most accurately as bimodal in nature. Chemotherapeutic agents and vitamin C and other antioxidants, dietary or administered, may interact

in a synergistic manner to reduce drug toxicity and enhance therapeutic efficacy. Conversely, many antineoplastic agents, as well as radiotherapy, rely on a mechanism of action employing focused exposure to intensified levels of free radicals, which may contribute to destruction of tumor cells, although many mechanisms are believed to be involved. The simultaneous administration of vitamin C with chemotherapeutic agents or radiotherapy could theoretically diminish the therapeutic action of these interventions, to the degree that free-radical generation is central to the tumoricidal mechanism, and to the degree that ascorbic acid can quench the free radicals generated. Dietary sources of vitamin C and associated antioxidant nutrients are theoretically capable of exerting a similar activity. Such a judgment, however, assumes that the vitamin C or other nutrient is acting in its antioxidant mode and has not shifted to a pro-oxidant effect, and that such influence is inherently problematic. Moreover, nutrient form, dose, and mode of administration and clinical management, particularly timing and coordination of interventions (concurrent or alternating), can be decisive factors influencing effects and outcomes.

In two review papers, Prasad et al.[7] and Simone et al.[79] summarized the mechanisms that contribute to the effects of vitamin C and other antioxidants in the treatment of neoplastic diseases. First, "individual antioxidants such as vitamin A (retinoids), vitamin E (primarily alpha-tocopheryl succinate), vitamin C (primarily sodium ascorbate) and carotenoids (primarily polar carotenoids) induce cell differentiation and growth inhibition to various degrees in rodent and human cancer cells by complex mechanisms."[7] The proposed mechanisms for these effects in limiting carcinogenic processes include blocking destruction imposed by free radicals (thus protecting healthy tissue from damage), inhibiting protein kinase C activity (thus restraining tumor cell division and proliferation), inducing transforming growth factor-beta (TGF-β) and p21 genes, and inhibiting oncogene expression, prostaglandin E_1–stimulated adenylate cyclase activity, expression of c-myc, H-ras, and E2F, a transcription factor.[7,79] "Furthermore, antioxidant vitamins individually or in combination enhance the growth-inhibitory effects of x-irradiation, chemotherapeutic agents, hyperthermia, and biological response modifiers on tumor cells, primarily *in vitro*. These vitamins, individually, also reduce the toxicity of several standard tumor therapeutic agents on normal cells."[7] Notably, these papers and most research by experts in the field emphasize administration of multiple antioxidant nutrients concomitantly.

In reference to cisplatin, Weijl et al.[80] also proposed that "cisplatin-combination chemotherapy induces a fall in plasma antioxidant levels that may reflect a failure of the antioxidant defense mechanism against oxidative damage induced by commonly used anticancer drugs."

Vitamin C may aggravate cardiac toxicity of doxorubicin and related anthracyclines by mobilizing iron from storage sites and thus increasing levels of iron-catalyzed free radicals. Such adverse effects are less probable with liposome-encapsulated anthracyclines, which appear to have significantly less cardiac toxicity.

Research

The complex issue of concurrent administration of vitamin C and other antioxidants, whether as nutrients, herbs, or foods, during conventional therapy with antineoplastic agents in their various forms, as both monotherapy and polytherapy, has been the subject of protracted controversy and heated debate but minimal specific and substantive clinical research. Numerous surveys have found that the use of natural medicine and alternative therapies tends to be more widespread among individuals with cancer than in any other patient population, and that such use is more often self-prescribed or "nonintegrative," that is, lacking in coordination among the health care professionals and their respective therapeutic models.[81-90] Nevertheless, despite decades of attentions and a broad range of papers, offering mostly extrapolation, belief, opinion, and polemic, there have still been essentially no well-designed randomized trials of antioxidants versus placebo during the same chemotherapy or radiotherapy of adequate power to elucidate the fundamental clinical questions at hand or confirm any pattern of interaction that might be applied in a clinically consistent manner. Further, generalizations and extrapolations have especially limited value given the wide range of cancers among patients receiving oncological care and the diverse combinations of cancer drugs and radiotherapy employed in such interventions. Moreover, and perhaps most significantly in terms of developing a definitive research-based body of scientific evidence, any meaningful clinical trial would require that the diet of subjects be controlled for its antioxidant content. Adequately accounting for such confounding factors renders development of substantive clinical evidence extremely complicated, difficult, and expensive. The pervasive issue of patient disclosure of concurrent treatments and the need to cultivate a trusting therapeutic relationship further convolute professional collaboration, clinical decisions, and outcomes assessment. The following discussion of the key permutations of themes underlying possible and proven interactions between vitamin C and various forms of conventional chemotherapy (and radiotherapy) provides a clinical review of the available evidence, although some agents are discussed separately in other sections of this monograph.

Definitive research findings from large-scale, well-controlled, randomized clinical trials are lacking to demonstrate the long-term effects of combining chemotherapeutic agents and vitamin C or other oral antioxidants. The scattered evidence from in vitro and animal experiments and clinical reports of varying degrees of quality suggests, as concluded in a much-cited 1999 paper by Labriola and Livingston,[91] that "there is sufficient understanding of the mechanisms of action of both chemotherapeutic agents and antioxidants to predict the obvious interactions and to suggest where caution should be exercised with respect to both clinical decisions and study interpretation." However, in reviewing the data, it appears that the highly variable quality of available evidence and the wide range of agents involved render any consistent characterization and broad conclusions impossible, or at least premature. Instead, an overview and synthesis of the scientific evidence and clinical insight of professionals experienced in applying nutritional therapies in oncological care suggest that safe and effective therapeutic models are possible in certain cases and that flexible protocols are emerging, but that risks from mismanagement are real and continued research is critical.[7,7a,79,92-105] In such a comprehensive approach, each intervention constitutes a viable tactic in a comprehensive strategy employing integrative principles to craft individualized and evolving interventions based on the condition(s) being treated, agents being administered, and the characteristics and needs of the particular patient. This approach requires ongoing research and a posture of open-minded discovery, critical analysis, and flexible response in which all elements, whether conventional or nonconventional, chemotherapy or nutrient, are subject to rigorous standards of scientific evidence and equally vigorous clinical assessments of safety, tolerance, and outcomes.

Chemotherapy of many types (and all radiotherapy) leads to an increase in levels of reactive oxygen species, which stress the antioxidant defense system. Oxygen radicals are highly toxic, produce a variety of pathological changes through lipid peroxidation and DNA damage, and have been implicated in various disease processes, including carcinogenesis and aging.[106] For example, the cardiotoxicity of doxorubicin can be of rapid onset and endure for decades, often without cardiac complaints. In a longitudinal assessment of cardiac function in 22 patients treated with anthracycline for osteogenic sarcoma or malignant fibrous histiocytoma, Brouwer et al.[107] found systolic dysfunction in more than a quarter of the patients and diastolic dysfunction in almost half after two decades (22 years median). Moreover, cardiac dysfunction was progressive as measured at 9, 14, and 22 years.[107]

Many forms of chemotherapy release free radicals as a means of inducing irreversible tissue injury, and thereby reduce circulating levels of antioxidants. Weijl et al.[80] demonstrated that cisplatin combination chemotherapy induces a fall in plasma antioxidants of oncology patients with vitamin C, vitamin E, uric acid, and ceruloplasmin levels falling significantly; these levels returned to baseline levels before the start of the next chemotherapy cycle. Thus, although oxidative stress represents a significant causal or contributing factor in the development of tumors, its focused use in the form of chemotherapy and radiotherapy also provides a powerful tool in attacking cancer cells. These effects constitute one of the primary causes of adverse effects and toxicity associated with conventional antineoplastic therapy.

A variety of in vitro experiments, animal studies, and human trials have found that coadministration of vitamin C, usually in combination with other antioxidant nutrients, may enhance the therapeutic activity of chemotherapy in certain types of cancer and may reduce the adverse effects associated with such interventions.[7a,96,108-119] Ray et al.[120] observed that ascorbic acid could suppress cyclophosphamide-induced lipid peroxidation in vitro to a significant extent, as indicated by tissue levels of malondialdehyde, 4-hydroxy-2-nonenal, reduced glutathione, and nitric oxide. In animal experiments using mice and guinea pigs, Umezawa, Fujita, and associates found that vitamin C was associated with reduced severity of doxorubicin-induced cardiotoxicity and significantly increased life expectancy of mice and guinea pigs without interfering with the drug's antineoplastic activity.[121,122] Likewise, in an experiment using fibrosarcoma-bearing rats, Muralikrishnan et al.[123] found that coadministration of vitamin C mitigated lipid abnormalities typically associated with combined application of cyclophosphamide, methotrexate, and 5-fluorouracil (CMF), as applied in the treatment of breast cancer.[123]

In a prospective, placebo-controlled, randomized, double-blind pilot study involving 13 patients receiving "high-dose" chemotherapy and 12 patients receiving radiotherapy, Wagdi et al.[124] found that an antioxidant combination consisting of vitamin C, vitamin E, and *N*-acetylcysteine (NAC) protected against heart damage induced by chemotherapy without reducing the drug's effectiveness. For example, 46% patients in the placebo-chemotherapy group and 66% in the radiotherapy-placebo group showed a reduction in left ventricular ejection fraction (LVEF) of 10% or greater; in contrast, no patient in either antioxidant group group, plus chemotherapy or plus radiation, showed a fall greater than 10%, and most demonstrated significantly smaller change, if any. While cautioning that the "small number of patients in the study precludes a definitive statement," the authors concluded that these preliminary results "suggest efficieat cardioprotection by this nontoxic and inexpensive antioxidant combination, so larger studies are warranted for confirmation."

Babu et al.[125] reported a "salubrious effect of vitamin C and vitamin E" on tamoxifen-induced hypertriglyceridemia in postmenopausal women with breast cancer. They coadministered vitamin C (500 mg) and vitamin E (400 mg) for 90 days along with tamoxifen (10 mg twice daily). Among the "tamoxifen-treated patients, total cholesterol (TC), free cholesterol (FC), phospholipids (PL), free fatty acids (FFA), low density lipoprotein cholesterol (LDL) levels were decreased and the triglycerides (TG), ester cholesterol (EC), high density lipoprotein cholesterol (HDL) and very low density lipoprotein cholesterol (VLDL) levels were increased." However, subjects treated with combination therapy exhibited a reduction in total cholesterol levels, VLDL, and LDL, whereas "TG levels were significantly decreased and HDL, EC levels were significantly increased."[125]

Pediatric oncologists Kennedy et al.[126] performed a 6-month observational study of 103 children with acute lymphoblastic leukemia in which they demonstrated that low dietary antioxidant vitamin intakes are associated with increases in adverse effects of chemotherapy. Among their findings was the observation that greater vitamin C intakes at 6 months were "associated with fewer therapy delays, less toxicity, and fewer days spent in the hospital."

In a phase II study involving the combination of "antioxidants, both in the diet and supplemented, pharmaconutritional support, progestagen, and anti-cyclooxygenase-2," Mantovani et al.[127] demonstrated "efficacy and safety" in 44 patients with "cancer-related anorexia/cachexia and oxidative stress." They evaluated data on four variables (clinical, nutritional, laboratory, quality of life) in 39 "advanced" cancer patients, with "cancer-related anorexia/cachexia and oxidative stress," who completed 4 months of an integrative treatment regimen consisting of "diet with high polyphenols content (400 mg), antioxidant treatment (300 mg/d alpha-lipoic acid + 2.7 g/d carbocysteine lysine salt + 400 mg/d vitamin E + 30,000 IU/d vitamin A + 500 mg/d vitamin C), and pharmaconutritional support enriched with 2 cans per day (n-3)-PUFA (eicosapentaenoic acid and docosahexaenoic acid), 500 mg/d medroxyprogesterone acetate, and 200 mg/d selective cyclooxygenase-2 inhibitor celecoxib." They reported significant increases from baseline of body weight, lean body mass (LBM), and appetite; "important decrease of proinflammatory cytokines interleukin-6 (IL-6) and tumor necrosis factor-alpha, and a negative relationship worthy of note was only found between LBM and IL-6 changes"; and "a marked improvement" in quality of life, as assessed using several standard scoring systems. Of the 39 patients, 22 were determined to be "responders" or "high responders" at the end of the study. The authors concluded that "the treatment was effective and more importantly was shown to be safe," and that "therefore, a randomized phase III study is warranted."[127]

As to the general issue of coadministering antioxidant agents during chemotherapy, it is noteworthy that several pharmacological agents are used within conventional care specifically for the protective effects of their antioxidant activity. Mesna (Mitexan, sodium 2-mercaptoethane-sulfonate) protects the urinary tract from the urotoxic effects of oxazaphosphorine cytostatics (ifosfamide, cyclophosphamide, sufosfamide, and trofosfamide) by forming a nontoxic additive compound with acrolein, a chemotherapy metabolite, which is spontaneously formed in the urine from the primary metabolites eliminated through the kidneys.[128,129] Dexrazoxane (Zinecard), a cyclic derivative of EDTA, has been prescribed as a cardioprotective agent based on its role in modulating

free-radical production by chelating free iron in doxorubicin-induced cardiomyopathy; coadministration permits significantly greater doses of doxorubicin to be administered to patients with greater tolerance and safety.[130-140] Amifostine (Ethyol) is a phosphorylated prodrug with antioxidant effects analogous to those of glutathione. It is selectively dephosphorylated by normal cells, which express much higher levels of the cleaving phosphatase enzyme than do malignant cells. Dephosphorlyation allows the drug to move intracellularly, thus selectively protecting normal cells from chemotherapy and radiation. Amifostine was initially approved to protect against renal injury by cisplatin in ovarian cancer patients, and approval was then extended to decrease the loss of salivary function from radiotherapy in head and neck cancer, although some oncologists use it in a broader context for chemoprotection and radioprotection.[141-146]

Birdsall et al.[147] and Cancer Treatment Centers of America conducted an exploratory trial to investigate effect of concomitant naturopathic therapies on clinical tumor response to external-beam radiation therapy for early-stage prostate cancer (tumor stages 1b through 2, N0M0). External-beam radiation therapy of up to 72 Gy was given to 22 patients on a conventional 8-week treatment regimen; the 13 patients in the naturopathic group received at least one antioxidant supplement, with antioxidant naturopathic treatments most frequently including green tea extract, melatonin, and a high-potency multivitamin, vitamin C, or vitamin E. "All patients were monitored for at least 12 months (range 12-42) and no patient received concomitant hormonal therapy." The investigators reported that in the patients "who did not receive naturopathic [antioxidant] treatments, the median pretreatment PSA level was 5.4 ng/mL, the median PSA nadir was 0.66 ng/mL, and the median time to PSA nadir was 16.0 months," whereas in the "patients who did receive naturopathic treatments, the corresponding values were 5.8 ng/mL; 0.59 ng/mL; and 16.0 months" (PSA, prostate-specific antigen). One tumor treatment failure occurred in the nonnaturopathic group "based on PSA elevation > 2 ng from nadir which occurred at 14 months"; there were no treatment failures in the patients who received concomitant naturopathic regimens. The authors noted as "also significant that 9/9 patients in the non-CAM group were considered to be low risk (based on pretreatment PSA levels of 4-10 ng) whereas 3 patients in the CAM group were classified as intermediate risk (PSA >10-20 ng) and 1 patient as high risk (PSA > 20 ng)" (CAM, complementary and alternative medicine). Thus, the authors concluded that "concomitant naturopathic treatment does not appear to inhibit the capacity of external beam radiation therapy to control localized prostate cancer, and does not interfere with either the magnitude of the response, the velocity of the response, or its durability for at least 1 year." They added that these "results provide definitive evidence that antioxidant-based CAM modalities, designed to improve patient tolerance, quality of life, and possibly improve survival, do not inhibit tumor responses that depend on oxidative [tumor] killing mechanisms elicited by external beam radiation therapy."[147] Although encouraging, this small, retrospective study did not have sufficient power to draw any statistically significant conclusions. Similar studies involving much larger groups of patients receiving radiotherapy are warranted.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Further research with large, well-designed clinical trials is essential, but vitamin C therapy is already playing a role in many cancer treatment protocols, employing multiple therapeutic modalities within an integrative clinical strategy. Physicians and other health care professionals may consider reviewing the potential for such synergistic therapies with appropriate patients and provide referral information to centers specializing in such integrative approaches. Self-administration of vitamin C by patients during conventional chemotherapy is not advised, and health care providers should caution patients against initiating this outside the context of close supervision and regular monitoring by health care professionals trained and experienced in these practices.

In clinical practice, health care professionals specializing in multidisciplinary oncological care often consider "pulse therapy" as a safe and effective means of administering vitamin C, antioxidants, and other nutritional support with conventional antineoplastic treatment. As discussed at numerous professional conferences, this technique typically involves cessation of nutrient administration just before delivery of a large chemotherapeutic bolus or radiation treatments, followed by reintroduction of high-dose antioxidants (e.g. IV ascorbate, NAC). This alternating dosing approach allows maximum cytotoxic effect on tumor cells (without potential interference by simultaneous pharmacological-dose nutrient input) while enabling patients to benefit from the protective and restorative effects of the nutrient support at appropriate intervals.[148,149] Juices made from foods rich in antioxidants may also be administered during the nutrient therapy phase, and conversely, prudence suggests their avoidance during nutrient-withdrawal phases.

Cimetidine and Related Histamine (H_2) Antagonists

Evidence: Cimetidine (Tagamet; Tagamet HB).
Extrapolated: Famotidine (Pepcid RPD, Pepcid, Pepcid AC), nizatidine (Axid, Axid AR), ranitidine bismuth citrate (Tritec), ranitidine (Zantac).
Similar properties but evidence lacking for extrapolation: Proton pump inhibitors: Esomeprazole (Nexium), lansoprazole (Prevacid, Zoton), omeprazole (Losec, Prilosec), pantoprazole (Protium, Protonix, Somac), rabeprazole (AcipHex, Pariet).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:	Evidence Base:
2. Probable	○ **Preliminary**

Effect and Mechanism of Action

Cimetidine can bind to cytochrome P450 covering the active heme group. The cytochrome proves to be vital to hydroxylation reactions in human steroidogenesis. Serum hydrocortisone concentrations will decrease when CYP450 becomes blocked.[150] Ascorbic acid can prevent cimetidine-induced decrease of human serum hydrocortisone concentrations. Researchers, however, have not elucidated the mechanisms for this observed phenomenon.

Research

In a blinded, parallel, prospective, clinical trial, Boidin et al.[150] compared the effect of IV ascorbic acid on cimetidine-induced decreases in concentrations of serum hydrocortisone in 16 male adults undergoing major abdominal vascular surgery. Cimetidine is administered to surgical patients under anesthesia and is known to inhibit steroidogenesis. In contrast to patients receiving a placebo, in whom serum hydrocortisone concentrations decreased, patients receiving ascorbic acid

exhibited a significant increase in serum hydrocortisone concentration.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The available evidence suggests that surgeons consider the potential benefits of coadministering vitamin C, when using cimetidine in conjunction with major abdominal surgery, to reduce undesirable effects of cimetidine on cortisone levels and attendant implications for inflammation and recovery. Adverse effects from such concomitant application have neither been reported nor would be expected based on established scientific evidence available at this time. Further research and more conclusive findings from adequately powered clinical trials are warranted to determine the efficacy of this observed interaction. Moreover, since cimetidine is clinically used less often than newer H_2 blockers, investigation into whether this effect and interaction occur with other histamine (H_2) antagonists appears worthy of consideration.

Corticosteroids, Oral and Topical, Including Prednisone

Evidence: Corticosteroids, oral: Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol) prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort); corticosteroids, topical: cortisone eyedrops.
Extrapolated, based on similar properties: Other topical corticosteroids.
Similar properties but evidence lacking for extrapolation: Inhaled corticosteroids.
See also Cimetidine and related Histamine (H_2) Antagonists

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, Not Requiring Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **4. Plausible to 2. Probable**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Ascorbic acid is an important cofactor for both adrenal cortex and adrenal medulla and essential in the biosynthesis and metabolic regulation of certain steroid hormones.[151,152] However, exogenous hydrocortisone can inhibit cellular uptake of ascorbic acid as well as the normal accumulation of ascorbic acid by adrenal chromaffin cells.[153,154]

Ascorbic acid administration can increase serum hydrocortisone concentrations, particularly when steroidogenesis is inhibited by exogenous agents such as cimetidine.[150]

Exogenous glucocorticoids, in the form of oral corticosteroids, can increase urinary loss of vitamin C, as well as related nutrients such as vitamin K, selenium, and zinc.[155]

Research

Chowdhury and Kapil[156] found that administration of two doses of dexamethasone caused a "sharp decline" in testicular ascorbic acid and cholesterol levels in prepubertal rat tissues. This adverse effect was reversible by administration of DHEA (dehydroepiandrosterone), 80 μg, but not by lower doses (20 μg).

Mehra et al.[153] confirmed that cortisone eyedrops reduced the concentration of ascorbic acid in the aqueous humor and lens. They also found that simultaneous administration of vitamin A drops "neutralized" this adverse effect and mitigated the risk of drug-induced glaucoma or cataract.

Kodama et al.[157] have conducted extensive research into the relationships between vitamin C and the pituitary and adrenal glands, particularly in the context of immune function and chronic fatigue syndrome (CFS). In one series of four experiments using a healthy male volunteer, they investigated the "relation between ACTH, cortisol and vitamin C in plasma in the course of vitamin C infusion or injection treatment with and without the use of methyl-prednisolone annex, a suppressor of the homeostatic mechanism of the pituitary ACTH." First, they noted a three-phase response pattern in which a steroid-free vitamin C infusion treatment induced "distinct depletion of both cortisol and vitamin C from the circulation at the initial to moderate stages of the experiment,... a small surge of plasma cortisol at the middle stage, and... skyrocket-like rises of ACTH and cortisol of plasma at the terminal stage." Second, the "use of methylprednisolone annex in the vitamin C infusion set completely suppressed the emergence of the plasma ACTH/cortisol surges of the terminal stage, but not the small surge of plasma cortisol. The synthetic steroid also suppressed the depletion of vitamin C and cortisol of the initial to moderate stages." In a subsequent 9-month pilot trial, the authors compared the effects of a "dehydroepiandrosterone-annexed vitamin C infusion set" and an "annex-free vitamin C infusion set," with and without the oral intake of erythromycin and chloramphenicol, in the treatment of a male patient with CFS characterized by persistent pneumonia signs and dermatomyositis. They reported that the "megadose" vitamin C–antibiotic combination produced improvement for 3 months, followed by a return of symptoms. However, the DHEA–vitamin C "infusion treatments together with the long-term antibiotics treatment, as conducted in the 3rd stage...led to substantial extinction of pneumonia signs (leucocytosis, tachycardia, etc.)." They also observed that the DHEA-C-antibiotic "treatment markedly increased the excretion of both 17-ketosteroids and 17-hydroxycorticosteroids in the urine" and suggested that the DHEA administered "was converted to testosterone, which in turn made a contribution to the control of CFS." These authors concluded that the results "could be taken as evidence to indicate that the new vitamin C infusion treatment effectuates the clinical control of CFS by fortifying the endogenous activities of both cortisol and testosterone."[157]

Kodama et al.[158,159] have continued their research with several studies of this vitamin C–DHEA infusion method, usually with antibiotic therapy, in the treatment of many patients in Nagoya, Japan, with CFS characterized by interstitial pneumonia and autoimmune processes. In overview, they stated that the "merit of our treatment system is to create a new hormonal environment to improve the state of immunodeficiency by use of a non-steroid substance—vitamin C—which encounters little resistance from the feedback mechanism of steroid metabolism in the in vivo system."

Report

Masugi et al.[160] published a case report describing the beneficial effects of combining ascorbic acid and methylprednisolone pulse (mp) therapy in the treatment of a patient with idiopathic

thrombocytopenic purpura who had not responded adequately to treatment with methylprednisolone alone. They concluded that the "effect of this combination therapy seems to be better than MP therapy alone" and suggested that such coadministration is worth further examination as another therapeutic choice due to its fewer secondary effects than the usual regimen of corticosteroids, splenectomy, and other immunosuppressive drugs."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing oral corticosteroids, especially for extended periods of therapy, are advised to consider the potential depleting effects of these medications on the status of vitamin C (and other vital nutrients) and resultant adverse effects on immune and adrenal function. Although conclusive evidence from adequately powered human trials is lacking, the available data indicate that such coadministration of vitamin C may mitigate certain adverse drug effects, particularly impaired healing response, and could enhance treatment efficacy and tolerance. A daily dose of 500 to 1500 mg vitamin C constitutes a typical level of nutrient support and would generally be considered safe in most patients. Ascorbic acid infusions may be appropriate in some cases but require specialized training and monitoring. Further clinical trials focused on reducing adverse effects and enhancing therapeutic outcomes, as well as safety and protocols for determining the appropriateness of such coadministration, are warranted.

Cyclosporine

Cyclosporine (Ciclosporin, cyclosporin A, CsA; Neoral, Sandimmune, SangCya).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**
⊕✗ **Bimodal or Variable Interaction, with Professional Management**
✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability:
4. Plausible or
2. Probable

Evidence Base:
○ **Preliminary** or
◉◉ **Emerging**

Effect and Mechanism of Action

The use of cyclosporine as an immunosuppressive agent in the treatment of allograft patients presents with a significant incidence of adverse effects, particularly nephrotoxicity. The risk of such events is heightened because the drug is poorly bioavailable (~30%). Some individuals are unable to achieve or maintain therapeutic cyclosporine blood levels. Further, the antioxidant activity of vitamin C may provide protective support against the reactive oxygen species induced by the drug's action and the lipid peroxidation products suspect in its toxic effects within the kidneys. Concomitant administration of vitamin C during cyclosporine therapy may enhance bioavailability and decrease the clearance and steady-state volume of distribution of the drug, as well as enabling a reduction in adverse effects and cost. Such a supportive interaction could potentially allow for decreased dosage levels of the medication. Vitamins C and E have also been used as adjunctive therapy in the context of transplants on the basis that they might slow progression of transplant-associated arteriosclerosis.

Research

Parra Cid et al.[161] reported that antioxidant nutrients, including vitamin E, may protect against cyclosporine A nephrotoxicity.

In a retrospective study of data on 22 consecutive heart transplant patients, reduced trough levels of cyclosporine were observed in those who took twice-daily doses of 500 mg vitamin C and 400 IU vitamin E, compared with other patients. Although no other interactions were found between the antioxidants and cyclosporine, cyclosporine trough levels decreased from 136 to 103 ng/mL in the first 2 weeks after antioxidants were administered. The decrease in trough concentrations averaged 25% but was as high as 60% in some patients. The researchers concluded: "We also don't know what the mechanism of this interaction is, so that should be studied in a more detailed analysis."[162]

On a practical level, many substances interact with cyclosporine, and because of its erratic pharmacokinetics, drug levels are routinely used to determine doses. With proper monitoring, any such interactions can be readily corrected by titration of the drug doses. Cyclosporine is a classic CYP3A4 intestinal enzyme substrate; some physicians routinely administer cyclosporine with grapefruit juice (which contains a CYP3A4 enzyme inhibitor) to reduce drug costs because a smaller dose of the drug will produce a higher blood level from a reduction in the first-pass drug metabolism by intestinal CYP3A4 enzyme. Vitamin C, or the combination of vitamins C and E, may have various effects on cyclosporine pharmacokinetics, but more research is needed to establish this.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Individuals undergoing immunosuppressive therapy with cyclosporine may benefit from coadministration of vitamin C and possibly other antioxidants such as vitamin E. Such adjunctive therapy may reduce adverse effects but would require vigilant drug level monitoring and drug dosage adjustment as necessary. Effective care of these patients will require active collaboration among physicians trained and experienced in both conventional pharmacology and nutritional therapeutics within an integrative therapeutic strategy. Given that vitamin C and allied nutrients might alter cyclosporine absorption and pharmacokinetics and that a wide range in individual responses has been reported, drug levels should be checked regularly, perhaps more frequently than customary, starting at 2 weeks. Among vitamin C–rich foods, unsupervised intake of grapefruit juice in particular is strongly contraindicated in patients taking cyclosporine because of effects on pharmacokinetics and drug levels.

Desferoxamine and Related Chelating Agents

Desferoxamine (Desferrioxamine mesilate, desferoxamine mesylate; Desferal).

Similar properties but evidence lacking for extrapolation: Deferasirox (Exjade); EDTA, ethylenediaminetetraacetic acid.

Effect and Mechanism of Action

In general, vitamin C can slightly to moderately increase absorption of nonheme iron; it also modulates iron transport and storage in the body. Iron overload may theoretically result from coadministration of iron and vitamin C in patients genetically (hemochromotosis) or medically (frequent RBC transfusions) predisposed to it. Conversely, high iron levels or iron administration can reduce blood levels of ascorbic acid, a water-soluble antioxidant as well as a reducing agent, through oxidation. Administration of vitamin C can enhance the activity of deferoxamine in excreting iron, even at low levels such as 200 mg daily, but with dose-dependent enhancement particularly in the 750 to 2000 mg dose range.[163]

Ascorbic acid is reported to enhance the toxic effects of deferoxamine, but no mechanism of action has been confirmed. Ascorbate has been proposed to induce cytotoxicity from iron-catalyzed oxidation, even in iron-deficient medium, but these in vitro findings of a pro-oxidant action of ascorbate in the context of free metal ions do not correlate with generally accepted observations under physiological conditions in humans.[164-166] Complications involving left ventricular dysfunction are reported to be of particular concern, and its occurrence is purported to be rapid in onset and severe.

Research

Hussain et al.[163] investigated the effect of dose, time, and ascorbate on iron excretion after subcutaneous desferrioxamine in a series of experiments involving 13 patients with beta-thalassemia major and one with congenital sideroblastic anemia, all of whom were receiving regular blood transfusions. After establishing that midlevel doses (1500 or 2000 mg) of desferrioxamine were more effective than lower doses (750 mg), with higher doses (4000 mg) showing a variable response, these researchers found that concomitant ascorbic acid therapy was invariably associated with increased iron excretion after subcutaneous desferrioxamine (D.F.). "In twelve studies at different dose levels of D.F., ascorbate therapy was associated with increased iron excretion ranging from 24 to 245%." They concluded that "in most patients with transfusional iron overload subcutaneous D.F over a 12 h period, at a dose ranging from 2 to 4 g daily with ascorbic-acid saturation, is at present the most satisfactory method of removing excess iron."

Coadministration of ascorbic acid is reported to enhance the toxic effects of desferoxamine, but evidence from large human trials is lacking to confirm any deleterious effect of vitamin C on iron status in patients with iron overload being treated with desferrioxamine. However, published reports have described a few incidents of clinically important, transient deterioration of left ventricular function in patients receiving 500 mg/day of ascorbic acid concurrent with iron chelation therapy. Henry et al.[167] have documented echocardiographic abnormalities in the majority of patients with transfusion-dependent anemia and secondary myocardial iron deposition. Nevertheless, the authors reported that they subsequently "observed a reduction in ejection fraction in several of the patients at National Institutes of Health following the addition of ascorbic acid to a program of iron chelation with intramuscular desferrioxamine." Also, "discontinuation of the ascorbic acid has been followed by a return to normal left ventricular function in all but one patient."[167]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The coadministration of vitamin C with parenteral agents, especially desferoxamine, may enhance therapeutic efficacy by increasing iron excretion, but rarely may also increase risks of left ventricular dysfunction or other significant adverse effects.

Many clinicians experienced in iron chelation therapy of iron overload states administer 500 mg of vitamin C an hour before beginning each desferal infusion to mobilize iron from storage sites and render it more available for chelation and subsequent excretion. Clinicians should monitor for cardiac decompensation, particularly in patients with preexisting cardiac disease. Administration of vitamin C after desferal injection may increase toxicity.

The limited state of the evidence and the mixed outcomes suggest the need for continued research through well-designed clinical trials. Particularly because deferasirox is orally active and a more potent iron chelator than parenteral desferoxamine, clinical studies of potential interactions, both positive and negative, between deferasirox and ascorbate should be performed.

Disulfiram

Disulfiram (Antabuse and Antabus; tetraethylthiuram disulfide.)

Effect and Mechanism of Action

Ethyl alcohol (ethanol) is metabolized through the activity of alcohol dehydrogenase, which is the primary enzyme involved in its oxidation, and the microsomal ethanol-oxidizing system (MEOS), a key metabolic pathway, and manifests its toxic effects throughout the body, but most profoundly in the central nervous system (CNS).[168] Disulfiram is frequently used in the treatment of alcoholism but has a high level of noncompliance and dropout because of adverse effects, especially those attributable to acetaldehyde toxicity.[169]

Administration of vitamin C, alone or in combination with nutrients such as L-cysteine, and vitamin B_1 may provide a period of almost complete protection against acetaldehyde lethality, although it may not completely abrogate acetaldehyde toxicity.[170] Moreover, IV vitamin C (typically 1 g) is among the supportive measures possibly indicated to restore blood pressure and treat shock in severe disulfiram reactions.[168,171,172]

Vitamin C and other antioxidants (e.g., NAC) can inhibit the cytotoxic effect associated with disulfiram. Chronic administration of disulfiram appears to cause axonal degeneration and neurotoxicity, "at least in part, due to the cytotoxic effect of the disulfiram-Cu(2+) complex formed endogenously." The "disulfiram-Cu(2+) complex induces apoptosis and perhaps necrosis at a late stage mediated by oxidative stress followed by sequential activation of JNK, caspase-3 and poly (ADP-ribose) polymerase degradation" in a time-dependent manner. This "death-signaling pathway" involves "decreased mitochondrial membrane potential, increased free radical production, and depletion of non-protein-thiols (glutathione)."[173]

Both disulfiram and vitamin C can support abstinence in a supervised alcohol abuse program. Gamma-glutamyl transpeptidase (GGT) can fall with disulfiram but rise with vitamin C.[169]

Research

Vitamin C has been studied and used clinically for more than 50 years in the prophylaxis and treatment of disulfiram-alcohol reactions.[171,172] In 1975, Sprince et al.[170] published a paper discussing the protective action of vitamin C and other nutrients against acetaldehyde toxicity caused by heavy drinking, but also associated with heavy smoking. Using a rat model, they found that ascorbic acid, L-cysteine, and thiamine (in paired combinations) provided the greatest degree of protection against acetaldehyde lethality, although no combination completely prevented acetaldehyde toxicity. These researchers proposed that these particular nutrients acted synergistically and recommended coadministration to "enhance their individual activity in the body."

In a randomized, partially blind, 6-month follow-up study involving 126 patients, Chick et al.[169] compared the efficacy of supervised disulfiram (200 mg) and vitamin C (100 mg) as an adjunct to outpatient treatment of alcoholics. "In the opinion of the (blinded) independent assessor, patients on disulfiram increased average total abstinent days by 100 and patients on vitamin C by 69, thus enhancing by one-third this measure of treatment outcome. Mean weekly alcohol consumption was reduced by 162 units with disulfiram, compared with 105 units with vitamin C, and the disulfiram patients reduced their total six-month alcohol consumption by 2572 units compared with an average reduction of 1448 units in the vitamin C group." The researchers also observed that serum GGT "showed a mean fall of 21 IU/l in patients on disulfiram but rose by a mean of 13 IU/l with vitamin C." Although there were "no medically serious adverse reactions," seven patients in the disulfiram group reduced their dose due to "unwanted" adverse effects and four withdrew from treatment; one subject receiving vitamin C withdrew. Nevertheless, two thirds of the patients receiving disulfiram asked to continue the treatment at the conclusion of the study period. Such findings suggest that clinical trials investigating coadministration of these agents is warranted as a potential means of enhancing therapeutic outcomes while preventing or reducing adverse effects.

Clinical Implications and Adaptations

Clinicians using disulfiram in the treatment of alcohol addiction are advised to investigate the administration of vitamin C for application in situations of complications caused by Antabuse. Research into vitamin C coadministration in a preventive and synergistic role may be warranted.

Effect and Mechanism of Action

Resistance to recombinant human erythropoietin (rHuEpo) is common in hemodialysis patients with functional iron deficiency. Adequate levels of available iron are necessary for optimal response to rHuEpo, but in some cases, parenteral iron can produce iron overload, thereby increasing morbidity and mortality rates. Functional iron deficiency is a condition in which iron supply is reduced to meet the demands for increased erythropoiesis. Consequently, rHuEpo hyporesponsiveness can occur patients who are iron-overloaded (ferritin level of 500-800 μg/L) but also in those with normal iron status.[174-177]

Intravenous ascorbic acid improves anemia in iron-overloaded, erythropoietin (rEPO)–hyporesponsive hemodialysis patients. Vitamin C participates in many aspects of iron metabolism, including uptake, transport, regulation, mobilization, utilization, and sequestration.[178-183] Patients undergoing hemodialysis tend to develop ascorbic acid deficiency resulting from lack of dietary intake, increased vitamin oxidation catalyzed by iron, and nutrient depletion during dialysis. Although administration of iron can exacerbate hemosiderosis, ascorbic acid can beneficially alter hemosiderin metabolism and effect hemosiderin deposits. Hemosiderin is a pathological deposition of iron in tissues, including the spleen, small intestine, and bone marrow. Ascorbic acid can potentiate the mobilization of ferritin stores from inert tissue stores and facilitate the incorporation of iron into protoporphyrin in iron-overloaded hemodialysis patients being treated with rHuEpo.[183-188]

Thus, ascorbic acid administration, usually IV, not only improves the therapeutic response to rHuEpo but also facilitates elimination of iron from stores without reducing functional iron levels, including risk of rapid decline after discontinuing parenteral maintenance iron.[189]

Vitamin C is generally thought to reduce oxidative stress generated by iron administration, particularly in compromised patients. However, concerns have been raised that high-dose (usually IV) ascorbic acid might act as a pro-oxidant.[190]

Research

Over several decades, researchers have investigated the relationships between vitamin C and iron with regard to erythropoiesis and hemosiderin metabolism. Ascorbic acid intake augments the absorption of nonheme iron from dietary sources and reduces ferric iron (Fe^{3+}) to ferrous iron (Fe^{2+}) by mobilizing iron from the ferritin crystal core.[180,181] Since the 1950s, scientists have recognized that ascorbic acid facilitates heme synthesis by incorporation of iron into protoporphyrin. Bothwell et al.[184] noted in 1964 that individuals with scurvy often present with excessive iron deposits in the tissues. Nevertheless, evidence from well-controlled studies evaluating hemosiderosis and IV ascorbic acid is lacking. In the 1990s,

researchers determined that ascorbic acid enhances iron-induced ferritin mRNA translation by promoting the conversion of the iron regulatory protein (IRP) RNA-binding form to aconitase. Ponka and Kuhlback[185] reported a high incidence of ascorbic acid deficiency in hemodialysis patients caused by limited dietary intake and its removal during dialysis. Further, in studying individuals with iron overload, particularly hereditary hemochromatosis, Young et al.[186] observed generally low plasma levels of ascorbic acid, possibly as a result of increased iron-induced oxidation.

Using a rodent model, Srigiridhar and Nair[191] demonstrated that administration of alpha-tocopherol or a combination of ascorbic acid and alpha-tocopherol protects the GI tract of iron-deficient rats against iron-induced oxidative damage during iron repletion.

A number of studies of varying size and quality have investigated the efficacy and safety of ascorbic acid during EPO therapy, and most have found that such coadministration can promote increased iron utilization and counter anemia by facilitating iron release from inert depots and circumventing the defective iron utilization in chronic hemodialysis (HD) patients who are treated with rHuEPO. In a trial involving four iron-overloaded HD patients who had developed relative resistance to erythropoietin (and three of whom exhibited features of "functional iron deficiency") Gastaldello et al.[174] found that resistance to erythropoietin in iron-overloaded HD patients can be overcome by IV ascorbic acid (500 mg after hemodialysis, one to three times per week).

Tarng, Huang, and associates conducted a series of trials over several years investigating the efficacy of IV ascorbic acid for erythropoietin-hyporesponsive anemia in HD patients with iron overload. In a parallel, comparative study in 1998, Tarng and Huang[175] compared the effects of IV iron versus IV ascorbic acid for erythropoietin-hyporesponsive anemia in 50 HD patients with iron overload and hyperferritinemia. Patients in both the IV iron group and the IV ascorbic acid group were hyporesponsive to erythropoietin and functionally iron deficient. They administered IV ferric saccharate (100 mg) post-HD on five consecutive dialysis sessions in the first 2 weeks to the IV iron group, and IV ascorbic acid (300 mg) three times weekly for 8 weeks to the ascorbic acid group. After 8 weeks of ascorbate therapy, mean hematocrit significantly increased ($25.8 \pm 0.5\%$ to $30.6 \pm 0.6\%$), with a concomitant reduction of 20% in erythropoietin dose. Furthermore, a rise in transferrin saturation ($27 \pm 3\%$ to $48 \pm 6\%$) and serum iron (70 ± 11 μg/dL to 107 ± 19 μg/dL) paralleled the enhanced erythropoiesis. Although lacking statistical significance, serum ferritin fell modestly. In contrast, "intravenous iron therapy neither improved erythropoiesis nor reduced erythropoietin dose" during 12 weeks. Notably, after significant increases in indices of iron metabolism at 2 and 6 weeks, they decreased at 12 weeks and returned to the baselines. Thus, these findings demonstrated that IV ascorbic acid, but not IV iron, can effectively circumvent the functional iron-deficient erythropoiesis associated with iron overload in HD patients. The authors concluded: "Intravenous administration of ascorbic acid not only facilitates iron release from storage sites, but also increases iron utilization in the erythron."[175]

In a prospective trial involving 65 HD patients with iron overload (serum ferritin levels >500 μg/L) in 1999, Tarng et al.[192] investigated inadequate iron mobilization and defective iron utilization to determine criteria for prediction of a response to ascorbic acid treatment and establish guidelines for adjuvant therapy. They reported that 18 patients exhibited a "dramatic response" to IV ascorbic acid with a "significant increase in their hemoglobin and reticulocyte index and a concomitant 24% reduction in rEPO dose after eight weeks," as well as "a significant rise" in serum iron and transferrin saturation and a fall in erythrocyte zinc protoporphyrin (which accumulates when hemoglobin synthesis is impeded) and serum ferritin. In contrast to responders, controls and nonresponders showed no significant changes in mean values of hemoglobin, rEPO dose, iron metabolism parameters, and erythrocyte zinc protoporphyrin. Furthermore, by analyzing data from 18 responders and 19 nonresponders, the authors determined that erythrocyte zinc protoporphyrin at a cutoff level of more than 105 μmol/mol heme and transferrin saturation at a level of less than 25% were "more specific to confirm the status of functional iron deficiency in iron-overloaded patients" and served as the "two criterion values [that] had the highest accuracy to predict a response to treatment."[192]

Subsequently, in 2004, Tarng et al.[193] investigated the effects of IV ascorbic acid "on serum concentrations of soluble transferrin receptors (TfR) on the basis of the hypothesis that an increase of labile iron in the cytosol will lead to inhibition of TfR expression." First, applying a stepwise multivariate analysis to evaluate the interrelation between serum TfR and iron status in 138 HD patients, they confirmed that serum EPO and transferrin saturation were the two independent predictors for serum TfR in HD patients (high TfR levels are indicative of iron deficiency, functional or absolute). They also noted that the lower the serum EPO and the higher the transferrin saturation, "the lower the serum TfR in HD patients who are on maintenance rHuEPO treatment." Then, in a controlled study, 36 HD patients were randomly administered IV ascorbic acid (total dose of 2000 mg) or placebo (normal saline). Neither serum EPO nor ferritin levels changed significantly in either group. However, compared with presupplemental values, serum TfR levels significantly declined, and transferrin saturation rose within 7 days in ascorbic acid–treated patients before any apparent alteration in hematocrit values; in contrast, no such changes were observed in the placebo group. Notably, the trend of decreased serum TfR and increased transferrin saturation was similar among ascorbic acid–treated subjects with ferritin less than or greater than 500 μg/L. They concluded that "ascorbic acid status can significantly decrease serum TfR concentrations and increase percentage of TSAT, probably through alterations in intracellular iron metabolism."[193]

In a 6-month, randomized, double-blind, crossover trial involving 27 HD patients, Giancaspro et al.[194] investigated the effects of IV ascorbic acid on functional iron deficiency and whether this results in a better correction of anemia in patients with stable hemoglobin concentration and functional iron deficiency. During the treatment phase, subjects in each group received vitamin C, 500 mg intravenously three times a week for 3 months, with treatment discontinued during the other 3 months as control. Hemoglobin concentration rose in one group but dropped slightly in the other group. However, percentage transferrin saturation significantly increased, and ferritin fell significantly in both groups during their respective treatment phase. The rHuEpo dose was kept unchanged throughout the study. These investigators concluded that IV ascorbic acid "may partially correct" functional iron deficiency and consequently help rHuEPO-hyporesponsive anemia.

Similarly, in a trial involving 36 patients whose ferritin levels were higher than 500 μg/L and who needed more than 100 U/kg/week of rHuEPO, Sezer et al.[195] found that IV ascorbic acid "effectively overrides rHuEpo resistance in iron-overloaded hemodialysis patients." Using a two-phase structure,

they administered 500 mg IV ascorbic acid twice weekly to all the patients for 8 weeks during an initial phase and then, during an 8-week maintenance phase, separated the patients into groups, one of which received 500 mg ascorbic acid once weekly while the other group received no therapy. These researchers noted that the therapeutic response "remained stable in patient groups during the maintenance phase" and that in the six nonresponders, the hypochromic RBCs were less than 10%.

In a subsequent 12-month, prospective, randomized, double-blind, crossover study involving 63 subjects, Keven et al.[177] compared hemoglobin levels, weekly EPO dose, and ratio of EPO to hemoglobin (an index of EPO need) in patients treated with IV vitamin C, 500 mg three times a week, or with placebo over two consecutive 6-month periods. Subjects in both treatment groups, 20 patients (66.7%) in one group and 18 patients in the other group (64.3%), demonstrated positive response to vitamin C. Likewise, in both groups, vitamin C resulted in a significant increase in hemoglobin levels, a significant decrease in EPO-hemoglobin ratio, and increased transferrin saturation. In contrast, subjects in both groups exhibited no change in these parameters during their placebo phase. Although concluding that vitamin C "can be used as an effective adjuvant therapy to EPO in hemodialysis patients," including those with normal iron status, these authors added that "further studies are needed to determine possible predictors of hematologic response to vitamin C."

Lin et al.[196] have investigated the effects of low-dose IV ascorbic acid in diabetic ESRD patients with hyperferritinemia. In one trial they studied 22 chronic HD patients with type 2 diabetes in a single dialysis unit by comparing responses to different sequential treatment phases, including control period and post–IV ascorbic acid periods. The subjects received IV ascorbic acid, 100 mg three times per week for 8 weeks of treatment and 4 months of posttreatment follow-up. Hemoglobin and hematocrit increased significantly in the post–ascorbic acid period after 3 months compared with the control period, whereas mean corpuscular volume (MCV; red cell size, which is reduced in both absolute and functional iron deficiency) did not increase significantly. Also, serum ferritin significantly decreased at study completion and transferring saturation significantly increased at 1 month and further at 3 months. These researchers concluded that their findings demonstrated that short-term low-dose IV ascorbic acid therapy "can facilitate iron release from reticuloendothelial system but also increase iron utilization in diabetic hemodialysis patients with iron overload" and recommended that IV ascorbic acid be considered as "a potential adjuvant therapy to treat erythropoeitin-hyporesponsive anemia in iron-overloaded patients."[196]

Ogi et al.[196a] conducted a small trial contrasting the effects of IV ascorbic acid versus IV iron on functional iron deficiency in EPO-treated HD patients. Thirteen patients on chronic HD with functional iron deficiency (serum ferritin levels >300 ng/mL, serum iron levels <50 μg/dL) received IV injections of ascorbic acid, 100 mg three times a week, after HD until serum ferritin decreased to below 300 ng/mL (maximum, 3 months). The iron group (seven subjects) received more than 10 IV injections of saccharated ferric oxide (40 mg/dose) after HD. The seven patients of the control group received no iron preparation during the 3 months. Hemoglobin did not change in the ascorbic acid group during the 3-month period, but "serum iron increased significantly," from 37 to 49 ± 4 μg/dL, after 1 month ($p < 0.01$) and remained elevated until the end of the 3 months, and serum ferritin decreased significantly after 3 months. In contrast, hemoglobin and serum iron increased significantly in the iron group from the respective pretreatment levels during the 2-month period, and serum ferritin rose significantly after 2 months. Notably, recombinant erythropoietin dose remained stable for 3 months in all three groups. "These results suggest that in hemodialysis patients with a functional iron deficiency, treatment with intravenous ascorbic acid can prevent iron overload due to treatment with intravenous iron, and provide a useful adjuvant means of maintaining hemoglobin and serum iron levels."

A few studies found limited benefit and increased risk from ascorbic acid therapy in iron-overloaded, erythropoietin (rEPO)–hyporesponsive HD patients. In one trial involving 61 "unselected" HD patients, Taji et al.[197] found that patients who received 100 mg IV ascorbic acid after each dialysis session demonstrated no significant improvements in erythropoiesis or various measures of quality of life and "significantly higher adverse events" compared with controls. These researchers interpreted their findings as suggesting that ascorbic acid treatment would most likely provide no significant benefit to "unselected" HD patients (i.e., not selected based on predictive factors).

The safety and efficacy of oral ascorbic acid in patients receiving HD has also been discussed and remains controversial. Some reviewers of the scientific literature on vitamin replacement therapy in renal failure patients, such as Makoff,[198] have proposed that supplemental vitamin C intake be limited to 60 mg/day, derived from the RDA, based on the supposition that "inappropriately high supplementation of vitamin C may cause toxicities which exacerbate existing pathologies."[198] In an 8-week, open-label randomized parallel study, Chan et al.[199] compared the efficacy and safety of 250 mg oral ascorbic acid with 250 mg IV ascorbic acid, three times weekly, on hemoglobin (Hb), ferritin, and rEPO dose in 21 iron-overloaded HD patients. These researchers also examined the effect of 3 months of 500 mg oral ascorbic acid three times weekly compared with no treatment on Hb, ferritin, and rEPO dose in 153 HD patients. They noted that all patients had "severe" ascorbic acid deficiency (mean, 2.2 mg/L; normal range, 4.0–14.0), and that with treatment, the plasma ascorbic acid level "increased, but was not significantly different between the groups." Further, they found that there was no change in Hb, iron availability, and rEPO dose with either form of ascorbic acid, even in a subgroup of 30 subjects with anemia taking the oral form for a longer duration. Notably, although there was a significant increase in serum oxalate, there were no accompanying significant changes in left ventricular function or renal calculi formation. Despite this lack of improvement with either form in the smaller iron-overloaded group or the larger group of HD patients, the authors suggested that ascorbic acid (AA) "administration may still be warranted in view of severe AA deficiency in haemodialysis patients."[199]

In view of the positive studies of IV ascorbate previously discussed, it would seem that a careful search for a dose-response effect in such nonresponsive patients would be warranted, with careful monitoring for potential adverse effects, given the possibility of pro-oxidant effects of higher doses of ascorbate, and because HD patients are known to have high baseline levels of oxidative stress. Combining IV ascorbate with oral antioxidant administration of a broad spectrum of antioxidants, such as alpha-lipoic acid, tocopherols and tocotrienols, OPCs, anthocyanins and other plant-derived antioxidant polyphenols, astaxanthin, and other antioxidant carotenoids

(providing an extensive network of diet-derived antioxidant compounds that cover both lipid and aqueous physiological compartments), would seem a promising research avenue for this patient population.

Researchers and clinicians have expressed concern regarding the risk of iron overload after parenteral iron administration and the potential need to discontinue such therapy. Deira et al.[189] conducted a 6-month, prospective, randomized trial comparing IV ascorbic acid (AA, 200 mg three times weekly) versus low-dose desferroxamine (DFO, 1 mg/kg/week) in 27 HD patients with hyperferritinemia (>800 ng/mL) who had previously received parenteral iron (Ferlecit). "When Ferlecit was discontinued, functional iron did not vary and the epoetin resistance index (rhuEPO dose/Hb) was reduced by 21% in the i.v. AA group. In the DFO and control groups, functional iron levels fell. In the DFO group the epoetin resistance index increased by 20%, with no modifications in the control group." Overall, they observed no significant differences in iron loss or mobilization from dialysis, as well as a positive correlation between serum transaminases and ferritin, indicative of the hepatotoxicity associated with iron overload.

Other researchers have suggested that excessive dosing of ascorbic acid in HD patients with iron overload might "raise the risk of increasing free radical generation" and adversely influence serum ferritin levels because of a hypothetical pro-oxidant effect of ascorbic acid. Thus, in an experiment involving six healthy subjects and 29 HD patients, Chen et al.[190] studied the effect of IV ascorbic acid on oxidative stress parameters in blood samples. They reported that ascorbic acid presented "a strong antioxidant effect in DPPH chemical reaction," an index of free-radical scavenging activity. However, they also observed a "pro-oxidant effect when mixed with plasma or whole blood of healthy subjects and hemodialysis patients." This "pro-oxidant effect of ascorbic acid detected by LucCL [lucigenin chemiluminescence, which detects in vitro free-radical generation] was attenuated by various iron chelators and superoxide dismutase," and there was "no significant correlation between the responses of LucCL intensity to ascorbic acid administration and transferrin saturation." The changes of LucCL intensity were significantly higher in the ascorbic acid–treated group of HD patients than those in the control group. The ascorbic acid therapy produced significantly higher LucCL intensity in HD patients with elevated ferritin (≥600 ng/mL) than in those with ferritins less than 600 ng/mL. Although the "changes of LucCL intensity were positively correlated with serum ferritin level . . . , there was no significant correlation between the responses of LucCL intensity to ascorbic acid administration and transferrin saturation." These results are strongly suggestive that the presence of excess iron stores (as reflected by serum ferritin level) is a key factor in catalyzing oxidative stress (in vitro) in the presence of higher levels of serum ascorbate. The authors noted that the presence of iron-chelator-suppressible chemiluminescence in persons with higher ascorbic acid levels in the blood or plasma are "suggestive of free radical formation." However, they qualified this potential interpretation by adding that their data neither conclusively answered the question of "whether the findings occur *in vivo*" nor proved "that the free radicals generated *in vitro* lead to toxicity in patients." Overall, they concluded that their "results suggest that either lower parenteral dose or lower infusion rate of ascorbic acid may be more appropriate for adjuvant therapy in iron-overloaded uremic patients."[190]

The generally positive findings in these many experiments and preliminary studies have led researchers to recommend large-scale, prospective, and controlled trails to determine the long-term safety and efficacy of IV ascorbic acid therapy in iron-overloaded and functionally iron-deficient HD patients receiving epoetin alpha. The emerging trend in the research indicates that the need for determining patient characteristics predictive of iron-overloaded EPO hyporesponders most likely to achieve a beneficial response from ascorbic acid coadministration is of paramount importance. Based on their investigation into early prediction of response to intravenous iron medications in hemodialysis patients receiving rHuEPO, Chuang, Tarng, et al.[199a] suggested that changes in reticulocyte hemoglobin content (CHr) and reticulocytes in a high-fluorescence intensity region (HFR) at either 2 or 4 weeks "are superior to the conventional erythrocyte and iron metabolism indices and may serve as reliable parameters to detect iron-deficient erythropoiesis in HD patients undergoing rHuEpo therapy." As for predictors of response to coadministration of vitamin C, depleted nutrient status, elevated erythrocyte zinc protoporphyrin, elevated ferritin, and decreased transferrin saturation are generally considered the most important indicators.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians treating hemodialysis or other patients undergoing EPO therapy are advised to evaluate patients for possible predictors of iron-overload risk (generally from repeated RBC transfusions) and inadequate therapeutic response (usually either from absolute or functional iron deficiency). In such cases the coadministration of ascorbic acid, typically parenteral but possibly oral administration, may enhance the response to EPO therapy and reduce adverse effects of iron administration. Identification of iron-overloaded EPO hyporesponders before treatment or at the earliest possible stage provides the most effective means of determining whether ascorbate therapy is appropriate to any given patient, so as to reduce the probability of long-term adverse reactions to iron therapy, minimize risk of anemia, and enhance erythropoeitic response. Further studies are needed to determine possible predictors of hematological response to vitamin C.

Furosemide and Related Loop Diuretics

Evidence: Furosemide (Lasix).
Extrapolated, based on similar properties: Bumetanide (Bumex), ethacrynic acid (Edecrin), torsemide (Demadex).

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:	Evidence Base:
4. Plausible	○ **Preliminary**

Effect and Mechanism of Action

Ascorbic acid may amplify the bioavailability and activity of furosemide through several possible mechanisms. Vitamin C appears to enhance the GI absorption of furosemide, inhibit metabolism of furosemide at the gut wall, enhance the reabsorption of furosemide from the renal tubules, and increase the unionized fraction of furosemide at the receptor sites. Of these effects, reduced gastric first-pass

metabolism of furosemide with coadministration of ascorbic acid is most likely to contribute to the significant increase in the oral bioavailability.[200]

Furosemide acutely increases urinary excretion of oxalic acid and vitamin C (as well as vitamin B_6) in individuals with chronic renal failure. This effect could reverse the tendency in uremic patients toward accumulation of oxalic acid resulting in elevated plasma levels.[201]

Research

Using animal models, Lee and Chiou[200] observed that the combination of furosemide and vitamin C produced significant increases in oral bioavailability of orally administered furosemide as well as its diuretic and natriuretic effects. They observed increases in both urine output and excretion of unchanged furosemide after coadministering furosemide (20 mg intravenously or 40 mg orally) and ascorbic acid (150 or 500 mg orally) to dogs. They attributed this effect to reduced gastric first-pass metabolism of furosemide rather than increased furosemide absorption. They subsequently administered furosemide (6 mg orally) and ascorbic acid (up to 100 mg orally) to rats and reported that "amounts of furosemide remaining per gram of stomach after 30-min incubations of 50 micrograms of furosemide with 9000g supernatant fractions of stomach homogenates were increased significantly (48.5 vs. 42.4 micrograms) by the addition of 100 micrograms of ascorbic acid." In contrast, the percentages of the oral doses of furosemide recovered from the GI tract 8 hours after oral administration were similar without and with ascorbic acid coadministration. These and related findings led the authors to suggest that the "significant increases in the diuretic and natriuretic effects of furosemide with ascorbic acid could be the result of increases in the reabsorption of furosemide from renal tubules and increases in the unionized fraction of furosemide at the renal tubular receptor sites."[200]

Mydlik et al.[202,203] conducted a series of investigations of the effect of furosemide on urinary excretion of oxalic acid, vitamin C, and vitamin B_6 in patients with chronic renal failure (CRF). In one controlled clinical trial (1998), they observed an increased urinary excretion of oxalic acid, vitamin C, and vitamin B_6 during the first 3 hours after a single IV dose of 20 mg furosemide in a control group and in patients with CRF without dialysis treatment. This effect persisted for 6 hours in CRF patients without dialysis. The authors described a new positive side effect of furosemide—enhanced urinary oxalic acid excretion in the control group and in CRF patients without dialysis treatment—and a negative side effect of furosemide: increased urinary vitamin B_6 excretion in both groups. They recommended monitoring of vitamin C and vitamin B_6 in plasma "during long-term administration of large doses of furosemide to patients with chronic renal failure as deficiency of these vitamins could develop."[202] A year later these researchers published results of another trial in which they compared urinary excretion of vitamin B_6, oxalic acid, and vitamin C in three groups: 15 healthy subjects during maximal water diuresis, 12 patients in polyuric stage of CRF without dialysis treatment receiving a diet high in sodium chloride (15 g/day), and 15 patients in polyuric stage of CRF without dialysis treatment after IV administration of 20 mg furosemide. "Urinary excretion of vitamin B_6, oxalic acid and vitamin C significantly increased during maximal water diuresis while during high intake of sodium chloride the urinary excretions of these substances were not affected." The authors interpreted these results to suggest that "urinary excretion of vitamin B_6, oxalic acid and vitamin C depends on the urinary excretion of water" and to confirm their earlier findings that IV furosemide (20 mg) increases urinary excretion of vitamin B_6, as well as oxalic acid and vitamin C, in patients with CRF.[203]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing furosemide or related loop diuretics are advised to monitor levels of vitamin C and other nutrients and to supplement as indicated, particularly in patients with CRF and on dialysis. The evidence is limited but indicates that individuals prescribed furosemide might demonstrate greater efficacy from their medication with the simultaneous use of vitamin C. Further, these preliminary findings do not provide adequate guidelines for determining the appropriate dosage in a range of patients using furosemide. However, in most cases, a dosage of 1000 to 2000 mg of vitamin C two to three times daily could provide benefit without causing significant risk. If diarrhea results from ingestion of excessive vitamin C, the dose can simply be lowered to bowel tolerance.

Regular monitoring is warranted after introducing a new medication or nutrient or changing the dose or combination of any agents, and close supervision is especially critical in patients with compromised renal function. It may also be prudent to increase dietary intake of or to supplement the B-complex vitamins in patients taking furosemide because the drug increases excretion of vitamins B_1 and B_6.

HMG-CoA Reductase Inhibitors (Statins)

Evidence: Atorvastatin (Lipitor), lovastatin (Altocor, Altoprev, Mevacor), pravastatin (Pravachol), simvastatin (Zocor); combination drugs: Niacin and lovastatin (Advicor); simvastatin and extended-release nicotinic acid (Niaspan).
Extrapolated, based on similar properties: Fluvastatin (Lescol, Lescol XL), rosuvastatin (Crestor).

Effect and Mechanism of Action

Vitamin C, along with vitamin E and coenzyme Q10, plays a critical role in endogenous antioxidant activity, synthesis of glutathione, and inhibition of lipid peroxidation. Vitamin C is also protective of and participates in the regeneration of vitamin E. Conversely, statin drugs appear to exert an adverse impact on oxidative stress.

Concomitant intake of vitamin C and other antioxidants with conventional lipid-lowering agents may improve some lipid parameters, particularly low-density lipoprotein (LDL) cholesterol and triglycerides.[204]

Antioxidants, including vitamin C, may interfere with the high-density lipoprotein (HDL)-elevating activity of statin-niacin combinations, although the specific role of ascorbic acid in such potential interference, including possible mechanisms of action, have not been elucidated. Presumably, nutrient-rich foods could also impair the activity of such agents, if the hypothesis were to bear out under further investigation.

Research

The mixed evidence from clinical trials investigating the use of antioxidant nutrients during statin therapy indicates that scientific knowledge of the mechanisms of action and diverse effects of this common lipid management intervention, as well as its interaction with vitamin C and other nutrients, is incomplete. As part of the HDL Atherosclerosis Treatment Study (HATS), Brown, Cheung, and associates reported that coadministration of 1000 mg vitamin C, 800 IU alpha-tocopherol, 100 µg selenium, and 25 mg beta-carotene daily diminished the therapeutic activity of a simvastatin-niacin combination. In particular, this antioxidant combination appeared to interfere with the HDL-elevating activity of the statin-niacin combinations, especially with regard to Lp(A-I), even though statins alone generally lower HDL as well as LDL (with possible exception of atorvastatin).[205] In an accompanying paper focusing on coronary atherosclerotic plaques and the occurrence of a first cardiovascular event, the niacin-simvastatin combination was significantly superior to placebo with regard to average stenosis progression, although in participants also receiving antioxidants, this benefit was significantly attenuated, a finding interpreted as possible interference by antioxidants.[206] Notably, the specific role of vitamin C in such potential interference, including possible mechanisms of action, have not been presented in a precise and substantiated form. Moreover, the HDL increases were probably attributable to the niacin therapy because low-dose simvastatin monotherapy has only limited effects in raising the levels of HDL cholesterol and apolipoprotein (apo) A-I. Thus, one or more of the antioxidants might be interfering with niacin's ability to alter the expression of proteins responsible for the formation of HDL. Further, the findings derived from the population studied may have limited general relevance to individuals who have only elevated LDL cholesterol levels (and normal HDL levels) and to women, who made up only 13% of the cohort. Also, with regard to HDL status, there was no detriment to the antioxidants alone (i.e., given to a group without simvistatin/niacin) and actually a slight benefit, which, if involving thousands of patients as in the previous statin and the thrombolytic trials, might have become a trend or even statistically significant. Also of note is that statins block endogenous synthesis of ubiquinone (coenzyme Q10), and thus far no trials in this area have included coadministration of this important mitochondrial-protective antioxidant, with or without other antioxidants.

Subsequently, in a much larger, randomized, controlled trial involving more than 20,000 men and women with coronary artery disease (CAD) or diabetes, Collins et al.[207] found that the administration of an antioxidant combination (250 mg vitamin C, 600 mg vitamin E, and 20 mg beta-carotene daily) in conjunction with simvastatin did not impair the cholesterol-lowering effects of simvastatin over a 5-year period.

Arad et al.[204] conducted a double-blind, placebo-controlled, randomized clinical trial investigating whether coadministration of conventional lipid-lowering therapy and antioxidants could retard the progression of coronary calcification (as assessed by CT-determined calcium score) and prevent atherosclerotic cardiovascular disease (ASCVD) events. They administered atorvastatin (20 mg daily), vitamin C (1 g daily), and vitamin E (alpha-tocopherol, 1000 U daily), versus matching placebos, to 1005 asymptomatic, apparently healthy men and women age 50 to 70 with coronary calcium scores at or above the 80th percentile for age and gender. Notably, all subjects received concomitant aspirin (81 mg daily). The authors halted the trial prematurely, after more than 4 years, because no statistically significant effect was observed on progression of coronary calcium score. They concluded that the combined treatment "induced substantial and sustained reductions in LDL cholesterol and triglycerides but failed to achieve conventional levels of statistical significance in the reduction of either all ASCVD events or CAD events."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing statin therapy for dyslipidemia are advised to ask patients about their intake of vitamin C and other antioxidant nutrients. Monitoring for any adverse impact from high levels of antioxidant intake, including nutrient-rich foods, may be judicious in the event that a niacin-based formulation is used. No scientifically based and clinically useful conclusions have emerged to address the paradox of whether patients should be similarly advised of a potential "risk" from eating fruits and vegetables rich in vitamin C (as well as E and other antioxidants) as part of supporting cardiovascular health. Further research through well-designed, adequately powered, and clinically relevant trials are necessary to investigate these issues more conclusively. In such research the confounding factors of nutrient dose, source, and combination, as well as controlling for and focusing on food sources of antioxidant nutrients, need to be adequately accounted for to produce substantial findings with clinically relevant implications.

Indinavir and Related Protease Inhibitors

Evidence: Indinavir (Crixivan).

○ **Preliminary**

Effect and Mechanism of Action

Concomitant administration of ascorbic acid at doses of 1000 mg per day can reduce steady-state plasma concentrations of indinavir.[208]

Research

In a small, prospective, open-label, longitudinal, two-period time series involving seven healthy volunteers, Slain et al.[208] found that daily "high-dose" vitamin C (1000 mg/day) can reduce steady-state plasma concentrations of indinavir. They observed that mean steady-state peak concentration (C_{max}) of indinavir was significantly reduced (20%) after 7 days of vitamin C administration, and that the corresponding mean area under the curve (AUC 0-8 hours) was also significantly decreased

(14%). The mean minimum concentration (C_{min}) of indinavir was 32% lower in the presence of vitamin C, although not to a statistically significant degree. Oral clearance and half-life of indinavir were not significantly different. Notably, with regard to evolving standards of trial design, all "subjects were given a vitamin C content-controlled diet for 1 week before the study began and throughout the study period." Such levels of vitamin C intake are common in the HIV/AIDS patient population based on presumed enhancement of immune function. The authors noted that "subtherapeutic concentrations of antiretroviral agents have been associated with viral resistance and regimen failure" but cautioned that "the clinical significance of our findings remains to be established."[208] No data are yet available regarding lower intakes of ascorbic acid concurrently with indinavir or other protease inhibitors.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

These findings emphasize the need for physicians prescribing antiretroviral drugs to interview patients about treatments from other practitioners, as well as self-prescribed supplements and dietary programs, and to maintain an ongoing inventory of such concomitant factors. Although the research is limited in size, duration, and subject characteristics, its findings suggest that vitamin C used at pharmacological doses can reduce drug concentrations and potentially impair therapeutic efficacy. In cases where continued administration of vitamin C is deemed clinically appropriate or is the established choice of the patient, regular monitoring and dose titration of antiretroviral medications are essential. Well-designed and adequately powered clinical trials are warranted to investigate the potential risks and benefits of such coadministration, as well as compensatory integrative protocols.

Lansoprazole-Amoxicillin-Metronidazole (LAM) Triple-Therapy Regimen

Lansoprazole (Prevacid, Zoton); amoxicillin (Amoxicot, Amoxil, Moxilin, Trimox, Wymox); metronidazole (Dirozyl, Flagyl).

Related: HeliMet (Wyeth; discontinued in United Kingdom August 2005): Lansoprazole (Zoton), clarithromycin (Klaricid), metronidazole.

Effect and Mechanism of Action

Helicobacter pylori infection is recognized as a risk factor for peptic ulcers and gastric lymphoma/adenocarcinoma and an opportunistic pathogen in a compromised gastric environment. Ascorbic acid, the reduced form of vitamin C, is secreted by the normal stomach, supports a healthy gastric environment, including greater resistance to *H. pylori*, and may protect against gastric cancer. Ascorbic acid secretion in the stomach is impaired with increased occurrence of *H. pylori*, particularly as associated with chronic/atrophic gastritis.[209,210] Increased oxidation and a decreased secretion of ascorbic acid have been proposed as mechanisms for *H. pylori* infection and low ascorbic acid levels in gastric juice.[211]

Eradication of *H. pylori* using the lansoprazole-amoxicillin-metronidazole (LAM) triple therapy regimen enhances gastric vitamin C levels and recovery from gastritis.[209,211,212]

However, administration of ascorbic acid alone does not appear to eradicate *H. pylori* effectively or reduce gastric inflammation and may impair the therapeutic efficacy of triple therapy if coadministered, particularly against a metronidazole-susceptible strain of infection.[213]

Research

Several studies have found that successful treatment of *H. pylori* using LAM triple therapy correlates with restoration of normal ascorbic acid levels in gastric juice. Sobala et al.[209] investigated gastric juice ascorbic acid concentrations in patients participating in trials of *H. pylori* eradication for duodenal ulcer disease and intestinal metaplasia before and up to 15 months after attempted eradication. In 12 patients in whom *H. pylori* was successfully eradicated, they found that gastric juice ascorbate and total vitamin C concentrations and the ratio of gastric secretion to plasma vitamin C increased after treatment, with the increase greatest in subjects with high final plasma vitamin C concentrations. In contrast, in 22 subjects in whom *H. pylori* eradication failed, there were "no significant changes in juice or plasma concentrations after treatment." The authors concluded that "successful eradication of *H. pylori* improves secretion of vitamin C into gastric juice" and suggested that such an environment in the stomach enhanced protection against gastric cancer.

Subsequently, in a study involving 70 patients with *H. pylori*–associated gastritis before and after therapy, Ruiz et al.[211] reported that among patients who experienced reduction of gastric pH, "gastric juice ascorbic acid increased significantly after *H. pylori* clearance." They also observed that such benefical changes paralleled "improvement of the compromise of the gastric epithelium, reduction of the proportion of vitamin C composed by dehydroascorbic acid, and increase of the gastric juice/plasma vitamin C concentration gradient." Notably, in a manner consistent with an influential role of oxidative stress, they observed that "smokers had lower vitamin C concentrations in plasma and gastric juice before and after *H. pylori* clearance than nonsmokers."

Rokkas et al.[212] investigated gastric juice and plasma vitamin C levels in 88 dyspeptic patients, 58 of whom were *H. pylori* positive, before and after attempted eradication with LAM triple therapy. Before intervention, they observed that gastric juice vitamin C levels were statistically lower in *H. pylori* –positive patients than in the *H. pylori*–negative patients. Gastric juice vitamin C levels increased significantly in the 45 patients (77.6%) for whom triple therapy achieved eradication of *H. pylori*, reaching levels comparable to those among the 30 *H. pylori*–negative subjects. Moreover, these patients demonstrated a "significant... improvement of gastritis after eradication, which paralleled the elevation of gastric juice vitamin C levels." In contrast, they observed "no difference... in plasma vitamin C levels between *H. pylori*–negative and –positive patients or in the latter before and after *H. pylori* treatment." Thus, effective elimination of *H. pylori* using LAM triple therapy facilitated the restoration of normal levels of vitamin C secretion as part of successful treatment of dyspepsia and gastric pathology.

No research has been conducted to determine if increased intake and elevated blood levels of vitamin C might prevent initial *H. pylori* infection, which often occurs during childhood,

and reduce risk of peptic ulcers and stomach cancer. Nevertheless, using data from a random sample of almost 7000 American adults collected during the first phase of the Third National Health and Nutrition Examination Survey (NHANES-III), researchers have found that, after accounting for age, ethnicity, weight, and other factors, among white participants, those with the highest serum levels of ascorbic acid had a 25% lower prevalence of infection.[214] Thus, individuals with higher levels of vitamin C may have greater advantage in preventing *H. pylori* infection, peptic ulcers, and stomach cancer.

Although eradication of *H. pylori* using LAM triple therapy or other medications may enhance gastric vitamin C status and healthy stomach function, the concomitant administration of vitamin C may detract from therapeutic efficacy in recovery from *H. pylori* infection. In a trial involving 210 *H. pylori*–positive patients, Kockar et al.[215] compared the effect of several treatment regimes alone and in various combinations over 14 days in seven treatment groups (each with 30 patients). Of those receiving the standard treatment (lansaprasol 30 mg twice daily, clarithromycin 500 mg twice daily, amoxicillin 1 g twice daily), 20 (66%) achieved eradication. In contrast, 15 (50%) of those receiving ascorbic acid (1000 mg/day) in addition to the standard treatment achieved eradication, and only three (10%) did so among subjects treated only with ascorbic acid (1000 mg/day). The following year, in a randomized trial involving a total of 104 *H. pylori*–infected patients, Chuang et al.[213] compared the effects of LAM twice daily for 1 week versus LAM plus vitamin C (250 mg) and vitamin E (200 mg) twice daily for 1 week, followed immediately by vitamin C and E once daily for 6 consecutive weeks. Eight weeks after the completion of triple therapy, they assessed the patients for the effectiveness of *H. pylori* eradication and the histological severity of gastric inflammation. Intention-to-treat and per-protocol eradication rates in the LAM-plus-vitamin group were significantly lower (40% and 44%, respectively) than in the triple-only group (59.1% and 64.4%, respectively). Among patients infected with metronidazole-susceptible isolates, the LAM-only group had a higher intention-to-treat eradication rate than those in the LAM-plus-vitamin group (80% vs. 53.1%). However, the intention-to-treat eradication rates between the two groups were no different for the metronidazole resistance isolates. No significant differences in gastric inflammation were observed. The authors concluded that combining vitamin C and E with triple therapy failed to improve the *H. pylori* eradication rate and gastric inflammation and apparently reduced the eradication rate of triple therapy in patients with metronidazole-susceptible strain infection.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians are advised to recommend that individuals increase their consumption of vitamin C–rich foods as a means of reducing risk of *H. pylori* infection and as a possible means of mitigating the effects of infection in those with gastric disease who test positive for *H. pylori*. However, patients should be further advised to eliminate high-dose vitamin C intake while being treated with LAM triple therapy, to avoid any potential interference with the efficacy of the medication. It is known that low gastric pH is protective of *H. pylori*, which is why proton pump inhibitors to achieve neutral gastric pH are combined with antibiotics. From this preliminary research, prudence would suggest that ascorbic acid (and perhaps other organic acids capable of lowering intragastric pH) should be avoided during anti-*H. pylori* therapy. Related research indicates that coadministration of probiotic flora to restore gut ecology can enhance clinical outcomes.[216]

Levodopa, Carbidopa, and Related Antiparkinsonian Medications

Carbidopa (Lodosyn), levodopa (L-dopa; Dopar, Larodopa); combination drugs: levodopa and benserazide (co-beneldopa; Madopar); levodopa and carbidopa (Atamet, Parcopa, Sinemet, Sinemet CR); levodopa, carbidopa, and entacapone (Stalevo).

Effect and Mechanism of Action

Oxidative stress appears to play a significant role in the pathogenesis of Parkinson's disease (PD), and levodopa monotherapy may aggravate that stressor.[217-219] Individuals with PD tend to exhibit elevated levels of oxidative stress. However, L-dopa undergoes autoxidation (as does dopamine), thus generating reactive oxygen species and decreasing plasma antioxidants, and thereby contributes to levodopa-induced neurotoxicity.[220-222] In contrast, dopamine agonists act through several antioxidant mechanisms that confer neuroprotective effects, including slowing dopamine neuron degeneration and their influence on the nigrostriatal synthesis and release and turnover of dopamine.[223] Vitamin C and deprenyl are both effective in preventing the levodopa-induced inhibition of complex I activity, one of the enzymatic units of the mitochondrial respiratory chain, as demonstrated in different tissues from patients with PD.[224]

Ascorbic acid is a cofactor required in both adrenal steroidogenesis and catecholamine biosynthesis for conversion of dopamine to norepinephrine by dopamine beta-hydroxylase.[152,225] Vitamin C does not cross the blood-brain barrier but does enter the cerebrospinal fluid and can be found there in concentrations proportional to dietary intake.[226-228] Vitamin C is a highly effective antioxidant and, as such, has a particular affinity for hydroxyl radicals. Because hydroxyl radicals are considered especially significant in destruction of dopamine-producing cells in the substantia nigra, vitamin C may play an especially important role in preventing and slowing the progression of PD.

Most patients with PD are elderly and may experience difficulty with levodopa absorption because of the adverse effects of aging on the drug absorption processes. However, ascorbic acid can improve levodopa absorption, particularly in elderly PD patients with poor levodopa bioavailability. Consequently, coadministration of ascorbic acid with levodopa can enable reduction of levodopa dosage without diminishing its effectiveness.[229]

Research

Fahn[218,218a] found that Parkinson's disease patients administered "high-dosage" vitamin C and synthetic alpha-tocopherol

(3000 mg and 3200 IU daily, respectively) delayed the progression of their disease to the point where they needed L-dopa 2½ years later than subjects without nutrient support.

In an unblinded, uncontrolled clinical trial, Linazasoro and Gorospe[230] prescribed a solution of levodopa-carbidopa and ascorbic acid to 21 parkinsonian patients with motor complications. "Eight patients continued the treatment for a mean period of 16.8 months, experiencing substantial increases in the number of hours with good functional capacity." In particular, troublesome symptoms "such as dystonia and akathisia in 'off' periods disappeared in all cases in which they had been present," and the combined treatment was tolerated (i.e., in six of eight subjects who continued in the study and in four who ceased treatment late in the study). Furthermore, subjects reported substantial increases in the number of hours with good functional capacity and a reduction in "intake of other anti-Parkinsonian drugs." However, 13 patients (62%) "abandoned the study, citing exacerbation of biphasic dyskinesia as the main reason." These investigators concluded that the combination of levodopa-carbidopa and ascorbic acid "is a useful therapy in some Parkinsonian patients whose motor complications are not managed with conventional drug treatment" but cautioned that pretreatment screening "is probably of utmost importance" to ensure that this approach is not administered to patients with "intense biphasic dyskinesia."[230]

Buhmann et al.[228] studied markers of systemic oxidative stress and levels of hydrophilic and lipophilic antioxidants in plasma and cerebrospinal fluid (CSF) and investigated the influence of levodopa and dopamine agonist therapy on the oxidative status in patients with PD. When they compared samples from PD patients, patients with other neurological diseases (OND), and healthy controls they observed "increased oxidative stress, seen as higher levels of lipoprotein oxidation in plasma and CSF, decrease of plasma levels of protein sulfhydryl (SH) groups and lower CSF levels of alpha-tocopherol in PD patients compared to OND patients and controls." Furthermore, they found that, although levodopa treatment did not significantly change the plasma lipoprotein oxidation, levodopa "monotherapy tended to result in an increase of autooxidation and in a decrease of plasma antioxidants with significance for ubiquinol-10" (coenzyme Q10). In contrast, dopamine agonist therapy monotherapy was "significantly associated with higher alpha-tocopherol levels," and patients with dopamine agonist monotherapy or comedication with dopamine agonist exhibited "a trend to lower lipoprotein oxidation." Overall, these researchers concluded that their data supported "the concept of oxidative stress as a factor in the pathogenesis" of PD and "might be an indicator of a potential prooxidative role" of levodopa and a "possible antioxidative effect of dopamine agonists" in the treatment of PD.[228]

In a clinical trial involving sixty-seven elderly patients with PD, Nagayama et al.[229] compared various pharmokinetic parameters in plasma drug concentrations following ingestion of a tablet containing 100 mg levodopa (LD) and 10 mg carbidopa, with and without concomitant ascorbic acid (200 mg). They observed "significant increases" in AUC and C_{max} and a "significant reduction" in time to c_{max} (T_{max}) with addition of ascorbic acid in 25 patients with baseline AUC of 2500 ng/hour/mL or greater. The authors concluded that ascorbic acid "can improve LD absorption in elderly PD patients with poor LD bioavailability," and that levodopa therapy in combination with ascorbic acid "may be one of the strategies for PD treatment."

These emerging findings suggest that continued research through well-designed and adequately powered clinical trials is warranted to determine safety, efficacy, and predictors of patient suitability, as well as the benefits of combined application of coenzyme Q10, glutathione (parenteral), alpha-lipoic acid, tocopherols/tocotrienols, and other potentially synergistic antioxidant nutrients.

Reports

Numerous unqualified case reports have suggested that high-dose ascorbic acid may reduce adverse effects of levodopa therapy, including nausea or malcoordination. In a letter (1975), Sacks and Simpson[231] described a patient, previously unable to tolerate L-dopa because of severe nausea, whose condition greatly improved when ascorbic acid was coadministered. Subsequently, his condition rapidly deteriorated each time he received a placebo instead of vitamin C.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing antiparkinsonian drugs can reasonably consider the potential benefits of ascorbic acid coadministration as part of their therapeutic strategy. Advising patients to increase their intake of vitamin C and related antioxidants, in nutrient-rich foods or as combination nutrient formulations, may reduce risk or delay onset of Parkinson's disease, although conclusive evidence is still lacking. Limited evidence indicates that certain individuals may benefit from combining vitamin C at moderate doses (200-400 mg/day orally), along with coenzyme Q10 and vitamin B_6, with levodopa-carbidopa therapy. The effects of such nutrient support include improved drug absorption and reductions in nausea, malcoordination, and other common adverse effects associated with antiparkinsonian drugs. Such an integrative approach may be particularly indicated in patients whose motor symptoms are recalcitrant to standard drug therapy. However, careful evaluation of patient suitability and close supervision are warranted because certain individuals may experience exacerbation of biphasic ("on/off" phenomena) dyskinesia. Notably, ascorbic acid is sometimes used clinically in the treatment of levodopa toxicity.

Methotrexate

Methotrexate (Folex, Maxtrex, Rheumatrex).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

See Chemotherapy section.

Reports

Sketris et al.[232] reported the case of a female patient being treated for breast cancer with methotrexate and cyclophosphamide, but also taking propranolol, amitriptyline, perphenazine, and prochlorperazine. The patient experienced relief from the nausea caused by the cytotoxic therapy with the concurrent ingestion of 1 to 3 g of vitamin C daily. The authors noted that this nutrient coadministration produced little effect on the urinary excretion of methotrexate.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Coadministration of vitamin C with methotrexate (and cyclophosphamide) may potentially moderate adverse effects of this chemotherapeutic agent without diminishing its therapeutic

activity. However, the limited character of the available data on this specific interaction and the complexity of the broader interactions between antioxidants and chemotherapy render a generalized conclusion premature.

Nitroglycerin and Related Nitrates

Nitroglycerin (glyceryl trinitrate, GTN; Deponit, Minitran, Nitrek, Nitro-Bid, Nitro-Dur, Nitro-Time, Nitrodisc, Nitrogard, Nitroglyn, Nitrolingual, Nitrol, Nitrostat, Transderm-Nitro, Tridil), Isosorbide Dinitrate (ISDN, Isordil, Sorbitrate); combination drug: hydralazine and isosorbide dinitrate (BiDil); isosorbide mononitrate (Imdur, ISMN, ISMO, Isotrate, Monoket).

Interaction Type and Significance

☼ **Beneficial or Supportive Interaction, with Professional Management**

Probability:

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Organic nitrates have been used widely in conventional practice for the treatment of both coronary artery disease (CAD) and congestive heart failure (CHF), but the tendency of many individuals to build up tolerance to nitrates is an important factor limiting their clinical effectiveness. Nitroglycerin and the other organic nitrates are prodrugs that appear to undergo a biotransformation process to yield nitric oxide (NO) or some NO adjunct as their vasoactive metabolite. While providing clear benefits in acute care, nitrate tolerance develops, and these medications rapidly lose some of their hemodynamic activity and clinical effectiveness when applied as sustained therapy. Numerous investigations and ongoing debate have produced no conclusive knowledge of the mechanism(s) underlying nitrate tolerance. However, coadministration of vitamin C with nitroglycerin can help maintain the nitroglycerin-induced dilation response and changes in the orthostatic blood pressure by one or more possible mechanisms.

Increased formation of superoxide radicals may play a significant role in the development of nitrate tolerance in certain patients. Coadministration of vitamin C may help reduce or eliminate vascular tolerance and help maintain the nitroglycerin-induced changes in the orthostatic blood pressure during long-term nitrate therapy. Some evidence indicates that antioxidant activity and free-radical scavenging produces this beneficial effect, but other data suggest that oxidative stress is not a critical contributor to nitrate tolerance and that tolerance reduction by vitamin C may be caused by "a stabilizing effect on enzymes involved in the bioconversion" of glyceryl trinitrate (GTN) to NO.[233-236] Other research indicates GTN tolerance is "a metabolic syndrome characterized by mitochondrial dysfunction," based on evidence that "nitrate tolerance is mediated, at least in significant part, by inhibition of vascular ALDH-2 [aldehyde dehydrogenase] and that mitochondrial ROS [reactive oxygen species] contribute to this inhibition."[237]

Research

Using continuous IV infusion in a canine model in 1996, Bassenge and Fink[233] administered nitroglycerin (GTN 1.5 µg/kg/min), alone or in combination with ascorbate (55 µg/kg/min), as an antioxidant, for 5 days while monitoring hemodynamic parameters and measuring ex vivo platelet function. With GTN alone, they observed both an initial maximal coronary dilator response and a fall of left ventricular end-diastolic pressure (LVEDP), which "declined progressively and disappeared during the infusion period," and "a progressive, unexpected upregulation of platelet activity demonstrated by enhanced thrombin-stimulated intracellular Ca^{++} levels and increases in the microviscosity of platelet membranes (indicating enhanced receptor expression) associated with a progressive impairment in basal, unstimulated cGMP levels." In contrast, with the combination of GTN and ascorbate as antioxidant, "the dilator responses were maintained fully throughout the infusion period," and adverse changes in platelet activity and microviscosity of platelet membranes were "prevented completely." Based on these findings, the authors concluded that "vascular tolerance is closely reflected by simultaneous changes in platelet function and further, that both can be prevented completely by appropriate antioxidants such as ascorbate."

In 1998, Bassenge et al.[234] conducted an experiment in which they monitored hemodynamic effects and tolerance development in nine healthy subjects randomly administered transdermal GTN (0.4 mg/hour), oral vitamin C (500 mg), or the combination, three times daily for 3 days. With GTN alone, they observed "an immediate rise in arterial conductivity (a/b ratio of dicrotic pulse), but within 2 d of initiating GTN, the a/b ratio progressively decreased and reached basal levels," followed by "a progressive loss of the orthostatic decrease in blood pressure." In contrast, "coadministration of Vit-C and GTN fully maintained the GTN-induced changes in the orthostatic blood pressure, and the rise of a/b ratio was augmented by 310% for the duration of the test period." Furthermore, changes in "vascular tolerance in GTN-treated subjects were paralleled by upregulation of the activity of isolated platelets, which was also reversed by Vit-C administration." The authors concluded that these findings demonstrate that coadministration of vitamin C "eliminates vascular tolerance and concomitant upregulation of ex vivo-washed platelet activity during long-term nonintermittent administration of GTN in humans."[234]

Subsequently, Watanabe et al.[235] reported similar findings in two small trials focused on patients with established cardiovascular disease. They found that coadministration of oral vitamin C (2 g three times daily) with nitroglycerin prevented attenuation of development of nitrate tolerance in a randomized, double-blind, placebo-controlled trial involving 24 healthy volunteers and equal number of patients with ischemic heart disease.[238] They also demonstrated the preventive effect of ascorbate on the nitrate tolerance in another randomized, double-blind, placebo-controlled study involving 20 patients with CHF.

An in vitro experiment conducted by Hinz and Schroder,[236] however, suggests that the ability of vitamin C to attenuate nitrate tolerance occurs, at least in part, independently of its antioxidant effects. First, using LLC-PK1 kidney epithelial cells, they observed that a 5-hour "pretreatment with glyceryl trinitrate (GTN) resulted in substantial desensitization of the intracellular cyclic GMP response to a subsequent 10-min challenge with GTN (1 microM)." They noted that "GTN-tolerant cells were fully sensitive to the spontaneous nitric oxide (NO) donor spermine NONOate, which does not require enzymatic bioactivation." In contrast, cyclic GMP stimulation by GTN was "up to 3.1-fold higher when vitamin C (1-10 mM) was present during the pretreatment period." However, they also noted that "other oxygen radical scavengers such as tiron or dimethylsulfoxide and the NO scavenger PTIO left tolerance induction unaltered." The authors

concluded that these collective data "suggest that reactive oxygen species or NO do not contribute to the development of nitrate tolerance" and proposed that reduction of nitrate tolerance by vitamin C "may be due to a stabilizing effect on enzymes involved in the bioconversion of GTN to NO."

Subsequently, however, other research data have suggested, and evidence from an experiment using an in vivo model of nitrate tolerance supports the hypothesis, that the denitrification of organic nitrates is mediated by mitochondrial aldehyde dehydrogenase (ALDH) and that dysfunction of this enzyme is an important cause of tolerance. In particular, using a rat model, Sydow et al.[237] have observed that GTN infusions "were accompanied by decreases in vascular ALDH-2 activity, GTN biotransformation, and cGMP-dependent kinase (cGK-I) activity." In a related in vitro experiment using cultured endothelial cells, they demonstrated that "GTN increased the production of reactive oxygen species (ROS) by mitochondria, . . . these increases were associated with impaired relaxation to acetylcholine, [and] antioxidants/reductants decreased mitochondrial ROS production and restored ALDH-2 activity." Based on these multiple findings, the authors suggested that "nitrate tolerance is mediated, at least in significant part, by inhibition of vascular ALDH-2 and that mitochondrial ROS contribute to this inhibition," and therefore, "GTN tolerance may be viewed as a metabolic syndrome characterized by mitochondrial dysfunction," which ascorbate is capable of preventing. Certain other compounds with antioxidant activity appear not to be able to do this, although as yet there has been no comprehensive evaluation of the important nutritional antioxidants. There are some hints of mechanisms involved in ascorbate's GTN tolerance prevention, but this remains somewhat unclear.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing organic nitrates for more than acute therapy are advised to consider coadministration of ascorbic acid at a clinically effective dose, such as 400 to 800 mg three times daily or more, as a means of enhancing the therapeutic effectiveness of nitrate therapy by preventing nitrate tolerance, as well as providing other potential benefits in reducing cardiovascular risk, such as prevention of platelet activation by chronic nitrate administration. In acute situations, IV ascorbic acid may be indicated to optimize nitrate intervention and prevent the onset of nitrate tolerance; close monitoring and supervision by clinicians experienced in such interventions are essential to safety and therapeutic efficacy.

Despite limitations and apparent contradictions in scientific knowledge of the mechanisms involved in nitrate tolerance and vitamin C's ability to attenuate such developments, the available scientific literature tentatively supports the use of vitamin C during nitrate therapy as a means of attenuating such problematic developments. Moreover, although data showing possible or probable benefits are preliminary in many respects, no evidence yet suggests any adverse effects or impairment of drug activity from such concomitant therapy.

In patients requiring nitrate therapy for a sustained period, a comprehensive, evolving, and individualized therapeutic strategy is essential. Physicians prescribing long-acting nitroglycerin often advise patients to refrain from nitroglycerin for 10 to 12 hours each day as a means of reducing the tendency to nitrate tolerance. Furthermore, coadministration of L-arginine (substrate for nitric oxide synthase) and folic acid may also inhibit development of nitrate tolerance, although preliminary clinical trial evidence suggesting worse outcomes in post–myocardial infarction (MI) patients with L-arginine would argue against its use in this setting, pending larger and longer randomized clinical trials. The appropriateness of antioxidants in such an integrative strategy is controversial because the role of oxidative stress in cardiovascular disease in general and nitrate tolerance in particular remains unclear and the clinical application of antioxidants contentious. Further research through well-designed and adequately powered clinical trials is clearly warranted and strongly recommended.

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCep. 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).

Effect and Mechanism of Action

In a review of this possible interaction, Stockley[239] concludes that no mechanism has been established. Nevertheless, numerous hypotheses have been proposed over the past 30 years. Oral contraceptives (OCs) may cause increased ascorbic acid turnover in tissues and reduce plasma, leukocyte, and platelet ascorbic acid levels.[240-242] Conversely, ascorbic acid (in gram doses) may elevate plasma levels of ethinyl estradiol by interfering with the conjugation of ethinyl estradiol to its sulfate for excretion, but other evidence indicates that high-dose vitamin C does not interfere with the pharmacokinetics of ethinyl estradiol.[243-245] Paradoxically, multivitamins, including vitamin C, may play a role in incidents of contraceptive failure or breakthrough bleeding.[243,246,247] In such instances, ascorbic acid could theoretically cause elevated blood concentrations of ethinyl estradiol resulting from competition for sulfation; in contrast, "progestogens are only metabolised in the liver and have no significant enterohepatic recirculation."[248]

Research

The scientific data concerning interactions between OCs and vitamin C are limited, diverse, inconsistent and contentious. Overall, OCs may lower vitamin C levels in plasma and white blood cells (WBCs), whereas ascorbic acid may (or may not) elevate serum ethinyl estradiol levels.[259] However, changes in OC formulations over the past several decades, the use of vitamin C in conjunction with other nutrients, and the diverse characteristics of the patient populations render much of the available information obsolete or inappropriate for deriving valid generalizations. Moreover, the preponderance of unqualified case reports, the small size of the few relevant clinical trials, and the lack of any substantive evidence as to mechanisms involved collectively fail to provide a coherent body of findings of adequate quality to enable anything other than a cursory review of the scientific literature.

Numerous studies conducted in the mid-1970s produced findings indicating that OCs can adversely affect levels and functions of several key nutrients, including vitamin C. These original papers led to an extended reiteration of such conclusions in numerous editorials and reviews. In particular, researchers described lowered levels of ascorbic acid in plasma, leukocytes, and platelets in women using estrogen-containing OCs.[240-242,249-254]

Oral contraceptives can increase requirements of several key nutrients, including vitamin C, and may induce nutrient depletions in certain women, especially those with compromised nutrient intake or metabolic stressors. Based on research of OC effects on ascorbic acid metabolism in rhesus monkeys, Weininger and King[242] proposed that the observed reduction could be caused by increased ascorbic acid turnover in tissues. In a study involving 10 healthy young women who had taken OCs of the combined type for several cycles, Briggs and Briggs[255] initially observed "plasma concentrations of ascorbic acid and vitamin B_{12} below the range seen in a matched group of untreated women," whereas red blood cell (RBC) aspartate transaminase (AST) and glutathione reductase (GTR) "were less saturated by their essential co-factors." However, daily administration of "a high-potency vitamin B complex with vitamin C... restored all four biochemical indices of vitamin nutrition to the normal ranges." In a 1974 letter regarding a study by Sanpitak and Chayutimonkul[256] on OCs and riboflavin nutriture, Briggs[257] noted that the data showed "striking decreases in women taking oral contraceptives in all the water-soluble vitamins (C, B_{12}, ribotlavine, B_6), no change in vitamin E, but an increase in plasma retinol." In a subsequent prospective trial involving five lactating women, Cummings[258] found "little change in plasma ascorbic acid but a slight, non-significant, decrease in [breast] milk ascorbic acid levels," which was "promptly" corrected on initiation of supplementation with ascorbic acid.

In contrast, other researchers have produced findings indicating a lack of adverse effect of OCs on vitamin C, although in many cases, depletion of or adverse effects on other nutrients were confirmed. Prasad et al.[259] reported that plasma ascorbate levels were not affected by OC use. Subsequently, Mooij et al.[260] observed a similar pattern of depletion when they investigated the effects of OCs containing 30 µg of ethinyl estradiol on concentrations of several nutrients in serum and RBCs of 59 nonpregnant female volunteers, 28 of whom were taking OCs, for four cycles. Although "vitamin A levels were significantly higher and vitamin B_{12} levels were significantly lower in the group using OC,... comparison of the baseline values of vitamin total B_2, FAD, C, serum and red blood cell folate as determined on days 3 and 23 of the first cycle of the two groups compared revealed no significant differences." However, whereas "multivitamin and folic acid supplementation did not affect the concentrations of vitamin A and vitamin B_{12} with either group,... all other vitamins increased significantly" in both OC and control groups.

Effects inherently vary based on a woman's dietary intake, nutrigenomic makeup, and metabolic stressors, including nutrient depletion due to diet, lifestyle, and concomitant drug therapies. Thus, for example, Veninga[261] reported, "Among patients who are well nourished and nonsmokers, OC use does not appear to jeopardize vitamin C levels." As with other vitamins affected by OCs, biochemical deficiencies caused by the exogenous hormones may not manifest in any form easily ascertained by standard clinical parameters. In such cases, repletion of nutrient status through supplementation or enhanced dietary intake may produce beneficial effects even in the absence of overt clinical deficiency symptoms, as can occur with vitamin B_6. Nevertheless, opinions in clinical trials, editorials, and reviews range in their conclusions from recommendations for universal prophylactic multinutrient treatment with OC use to warnings that such nutritional support is unjustified or even potentially dangerous.[247,262]

Preliminary data suggesting a potential adverse effect on bioavailability of OCs has not borne up to deeper investigation. For example, Morris et al.[243] reported that oral intake of 1 g ascorbic acid substantially raised serum ethinyl estradiol levels (48% elevation at 24 hours) in women using OCs. However, in a definitive study of the influence of vitamin C on pharmacokinetics of ethinyl estradiol, Zamah et al.[244] found no effect of high vitamin C dosage on the systemic availability of ethinyl estradiol in women using a combination OC. In a blinded, randomized trial, 37 women using a combination monophasic OC (30 µg EE2 and 150 µg levonorgestrel) were administered concomitant daily doses of 1 g ascorbic acid, taken ½ hour before OC intake, during the first or second cycle of OC use, for two consecutive cycles. Using blood samples drawn 11 times over 12 hours on the first and fifteenth day of OC intake, they measured levels and calculated C_{max} and AUC (0-12 hours) of ascorbic acid, free and sulfated ethinyl estradiol, and a number of other parameters. Only 6-hour postintake samples were obtained on pill days 10 and 21. "No effect of ascorbic acid was observed" when "C_{max} and AUC values for EE2 and EE2-sulfate in cycles with and without ascorbic acid were evaluated statistically for days one and fifteen and the ratios of day 15/day 1 for each of the substances." They noted that only on day 15 "was there a significantly lower AUC for EE2-sulfate in the presence of ascorbic acid intake." These researchers interpreted the findings as demonstrating that "competition between ascorbic acid and EE2 for sulfation does not lead to an increased systemic availability of EE2 and is, therefore, unlikely to be of any clinical importance." They concluded: "Ascorbic acid can, therefore, be removed from the list of drugs interfering with the pharmacokinetics of ethinyl estradiol."[244]

Subsequently, in a study involving American women, Kuhnz, Zamah, et al.[245] reported the absence of an effect of high oral doses of vitamin C on the systemic availability of ethinyl estradiol in women using a levonorgestrel-containing (LNG) combination OC. They reported that "no effect of vitamin C was observed for any of the parameters investigated, concluding that "repeated oral administration of gram quantities of vitamin C does not impair the sulfation of hydroxylated metabolites of LNG." Furthermore, they noted "no observable effect on the serum protein binding of LNG and the concentrations" of sex hormone–binding globulin (SHBG)

and corticosteroid-binding globulin (CBG) in the serum. In a review, Shenfield[248] proposed that differences in the way OC formulations interact with diverse agents derives from ethinyl estradiol being "sulphated in the gut wall, hydroxylated and glucuronidated in the liver, and undergoes enterohepatic recirculation" while the "progestogens are only metabolised in the liver and have no significant enterohepatic recirculation."

For many years, clinicians, researchers, and patients have sought to determine whether the occurrence of cervical dysplasia might be associated with exogenous estrogens, particularly OCs, and nutrient intake, including vitamin C. In a case-control study involving 257 women with confirmed cervical dysplasia and 133 controls, Liu et al.[263] assessed dietary intake of various nutrients and risk factors. They found no significant correlation with OC use or other presumed risk factors, even after adjusting for their potential confounding effects. However, along with vitamin A, folate, and riboflavin, they did observe an increased risk for lower intakes of vitamin C compared with the highest intake level.

In unrelated but potentially relevant research, Huang et al.[264] found that low concentrations of 17β-estradiol, close to physiological levels, reduced oxidative modification of LDLs in the presence of vitamin C and vitamin E in vitro. In contrast to this activity of protecting LDLs from oxidation, 17β-estradiol monotherapy demonstrated no antioxidant effect.

Reports

Numerous contradictory and unqualified case reports present a range of potential interactions so broad and diverse as to suggest that the given outcome in any single case is highly individual and strongly influenced by numerous factors, such as diet, drug dose and formulation, health status, lifestyle factors, genetics, and concomitant drug and nutrient intake. No single conclusions can reasonably be drawn from these data.

Some reports suggest that vitamin C may impair the efficacy of OC steroids, leading to breakthrough bleeding and pregnancy. Morris et al.[243] published an unqualified report describing the case of one women taking the triphasic OC Logynon who reported heavy breakthrough bleeding within 2 to 3 days of ceasing her self-prescribed, 1-g daily dose of ascorbic acid. DeSano and Hurley[246] cited multivitamins, including vitamin C, as a contributing factor in contraceptive failure, although no mechanism was proposed or demonstrated.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing OCs are advised to consider possible adverse effects associated with such treatment and discuss these potential risks and means of preventing or reversing them with the patient. The available evidence indicates several possible interactions, with permutations ranging from depletion of several key nutrients, including vitamin C, to improbable occurrence of reduced drug efficacy. Dietary intake, tissue nutriture status, metabolic stressors, individual pharmacogenomic variability, and numerous other factors influence the probability and character of any potential interaction. In many cases, an actual interaction may not manifest any clinically significant changes, or such changes may be subclinical, subtle, or simply slow to exhibit obvious effects.

Prophylactic nutritional support may be appropriate for certain individuals, while monitoring over time may elucidate the need for supplementation based on clinical response to OCs. In many patients, nutritional support may relieve symptoms associated with OC use, even though no objective signs of nutrient depletion are evident. In such cases, ascorbic acid in the range of 200 to 500 mg twice daily, along with folic acid, vitamin B_6, and magnesium, can be beneficial in preventing or reversing adverse effects of OCs. More comprehensive clinical assessment is appropriate in individuals who develop premenstrual syndrome or other signs of estrogen accumulation, for whom stronger support of hepatic estrogen conjugation functions may be necessary. Although most evidence indicates that vitamin C supplementation is unlikely to interfere with the intended activity of OCs, it is always prudent to be watchful for any indications that vitamin supplementation might be impairing OC activity.

Propranolol and Related Beta-1-Adrenoceptor Antagonists (Beta-Adrenergic Blocking Agents)

Oral forms (systemic)

Evidence: Propranolol (Betachron, Inderal LA, Innopran XL, Inderal)

Extrapolated: Acebutolol (Sectral), atenolol (Tenormin); combination drugs: atenolol and chlortalidone (Co-Tendione, Tenoretic); atenolol and nifedipine (Beta-Adalat, Tenif); betaxolol (Kerlone), bisoprolol (Zebeta), carteolol (Cartrol), esmolol (Brevibloc), labetalol (Normodyne, Trandate), metoprolol (Lopressor, Toprol XL); combination drug: metoprolol and hydrochlorothiazide (Lopressor HCT); nadolol (Corgard), nebivolol (Nebilet), oxprenolol (Trasicor), penbutolol (Levatol), pindolol (Visken); propranolol combination drug: propranolol and bendrofluazide (Inderex); sotalol (Betapace, Betapace AF, Sorine), timolol (Blocadren).

Interaction Type and Significance

✗✗ Minimal to Mild Adverse Interaction—Vigilance Necessary

Probability:

5. Improbable

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Vitamin C may decrease the absorption and first-pass metabolism of propranolol to a minimal degree.

Research

In an experiment involving five healthy subjects, Gonzalez et al.[265] measured plasma concentrations and urinary excretion of propranolol and its metabolites following oral administration of a single 80-mg dose of propranolol with or without ascorbic acid pretreatment (2 g). Compared with controls, they observed that subjects treated concurrently with vitamin C exhibited decreases in maximum plasma concentration (C_{max}) of propranolol (28%), area under the propranolol concentration-time curve (from 0 to 24 hours; 37%), and the total amount of drug recovered in urine (66%). Furthermore, the time to reach C_{max} of propranolol was increased (from 1.9 to 2.7 hours). However, "no change in elimination rate was observed, indicating that ascorbic acid had affected both the absorption process and the first pass metabolism." The heart rate "decreased less when propranolol was administered with ascorbic acid" than in control subjects, but this was considered of "little biological importance." The authors proposed that ascorbic acid impaired both absorption and the metabolic conjugation of the propranolol. Overall, this interaction appears to be of minimal clinical significance.

Clinical Implications and Adaptations

Prudence suggests that physicians prescribing propranolol or related beta-adrenergic blocking agents caution patients to

separate oral intake of vitamin C from intake of the medication by at least 2 hours. The available evidence is limited and indicates that any effect that might occur would probably be of minimal clinical significance.

Tetracycline Antibiotics

Demeclocycline (Declomycin), doxycycline (Atridox, Doryx, Doxy, Monodox, Periostat, Vibramycin, Vibra-Tabs), minocycline (Dynacin, Minocin, Vectrin), oxytetracycline (Terramycin), tetracycline (Achromycin, Actisite, Apo-Tetra, Economycin, Novo-Tetra, Nu-Tetra, Sumycin, Tetrachel, Tetracyn); combination drugs: chlortetracycline, demeclocycline, and tetracycline (Deteclo); bismuth, metronidazole, and tetracycline (Helidac).

Interaction Type and Significance

⊕⊕⊕ **Beneficial or Supportive Interaction, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Concomitant intake of vitamin C can enhance bioavailability and elevate blood levels of tetracycline.[266,267]

Prolonged use of tetracycline may reduce blood levels of ascorbic acid and can interfere with the activity of vitamin C as well as folic acid, potassium, and vitamins B_2, B_6, B_{12}, and K, particularly in individuals with digestive pathologies or otherwise compromised health or nutritional status.[268]

Vitamin C may also protect against hepatic and renal toxicity occasionally associated with tetracycline therapy, as well as the much more common adverse effect of dental and oral discoloration.[269-271]

Research

As early as 1957, Freinberg and Lite[266] found that coadministration of 500 mg vitamin C with tetracycline increased blood levels of tetracycline. Similarly, Omray and Varma[267] reported that coadministration of vitamin C (100 mg/day) increased the bioavailability of tetracycline in experiments evaluating the pharmacokinetic parameters of tetracycline hydrochloride in healthy subjects.

Polec et al.[269] observed that ascorbic acid could exert a protective effect against tetracycline-induced nephrotoxicity. Naseer and Alam[270] subsequently reported a similar protective effect of ascorbic acid against nephrotoxicity and hepatotoxicity induced by oxytetracycline.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Limited evidence suggests that physicians prescribing tetracycline-class antibiotics consider the potential benefits of ascorbic acid coadministration, particularly with extended periods of administration and in patients with compromised nutritional status and hepatic or renal function. Nothing in the available data has been interpreted to suggest a significant probability of any adverse effect with coadministration, whereas the general trend in the literature suggests a supportive and possibly protective effect from concomitant vitamin C. In particular, prudence suggests that the possible protective effect against the discoloration of children's teeth by tetracycline (a relative contraindication for pediatric use) deserves consideration.

Although controversial, most advocates of vitamin C usage would further, and more fundamentally, recommend high-dose vitamin C for its direct effects on bacterial infection and the immune system. A supplemental (or moderate therapeutic) dose of vitamin C is usually in the range of 2000 to 4000 mg per day, in divided doses, although higher-dosage ascorbic acid therapy is relatively common.

Further research into the safety and efficacy of such purposeful coadministration is warranted, especially given the high incidence of self-prescribed vitamin C dosing during acute illnesses and the associated high probability of unsupervised self-administration.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Aluminum Hydroxide and Related Aluminum-Containing Antacids

Evidence: Aluminum hydroxide (Alternagel, Amphojel).

Related: Aluminum carbonate gel (Basajel), aluminum magnesium hydroxide sulfate; combination drugs: aluminum hydroxide, magnesium carbonate, alginic acid, and sodium bicarbonate (Gaviscon Extra Strength Tablets, Gaviscon Regular Strength Liquid, Gaviscon Extra Strength Liquid); aluminum hydroxide and magnesium hydroxide (Advanced Formula Di-Gel Tablets, Co-Magaldrox, Di-Gel, Gelusil, Maalox, Maalox Plus, Mylanta, Wingel); aluminum hydroxide, magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets).

See also Cimetidine and Related Histamine (H_2) Antagonists.

A consensus within the scientific literature recognizes that citrate, particularly from citrus juice or calcium citrate, can greatly enhance gastrointestinal (GI) absorption of aluminum from both dietary sources and aluminum-containing antacids, can elevate blood aluminum concentrations, and may lead to retention and increased aluminum concentrations in the liver, brain, and bones.[272-280] The pattern of increased aluminum toxicity from this well-documented interaction with citrate is particularly of concern in patients with renal failure. Notably, calcium citrate without aluminum antacids does not cause aluminum retention in patients with functioning kidneys.[281,282]

Although broadly observed in both humans and experimental animals, the mechanism of this effect of citrate is not well understood, and its extrapolation to ascorbic acid is supported by only limited clinical evidence. The formation of a highly soluble aluminium-citrate complex has been proposed. Nevertheless, there are no functional correlations between ascorbic acid and citric acid, the only two common traits being their presence in citrus fruits and status as organic acids.

In regard to the interaction between ascorbic acid and aluminum hydroxide, the evidence is more limited. In particular, the series of animal and human studies conducted by Domingo, Gomez, et al.[283-285] found that coadministration of vitamin C and aluminum hydroxide can lead to increased aluminum absorption and excretion. In two experiments using a rat model, they observed that among a range of eight acid compounds commonly found as dietary constituents, all eight substances "significantly increased the aluminum concentrations [from drinking water] in most of the tissues [liver, spleen, kidney, brain and bone], with ascorbic and citric acids showing the highest rate of aluminum accumulation."[283] Their primary conclusion was that because of "the wide presence and

consumption of the above dietary constituents, in order to prevent aluminum accumulation and toxicity we suggest a drastic limitation of human exposure to aluminum."[284] They also recommended: "Meanwhile, the diet of uremic patients should be carefully monitored."[283] More directly, in an experiment involving 13 healthy volunteers, they observed that oral administration of aluminum hydroxide (900 mg three times daily) along with ascorbic acid (2 g daily) for 3 days produced "a significant increase in urine aluminum excretion, presumably because of enhanced gastrointestinal absorption." Based on these findings, they cautioned against administration of ascorbic acid in patients with renal failure who are taking aluminum-containing antacids.[285]

Evidence thus far suggests that administration of ascorbic acid, possibly even at dietary levels, is inappropriate with the simultaneous use of aluminum-containing antacids and is particularly incompatible in patients with compromised renal function, especially those on dialysis, although probably not as dangerous as citrate. Further human research is warranted to determine parameters of risk in terms of dose of each substance, timing, and patient susceptibility characteristics in this potentially significant interaction. Pending further evidence from well-designed trials, health care professionals should advise healthy individuals to avoid aluminum-based antacids within 2 to 3 hours of food and drink that contain citrates, ascorbic acid, and other organic acids, as in soft drinks. However, the entire question of the necessity and safety of aluminum-containing antacids deserves scrutiny, because their inherent toxicity is ultimately more responsible for the risk in this possible interaction than is the vitamin C (or citrate), whether in food or supplemental form, or its effects on aluminum metabolism. In the meantime, with patients who need antacid therapy, calcium-based or magnesium-based antacids offer safer options within the conventional pharmaceutical repertoire. Notably, aluminum hydroxide has been used in renal failure patients as a phosphate binder but is less effective than calcium carbonate and is associated with aluminum retention, particularly in children and young adults with chronic renal disease, and can lead to aluminum bone disease.

Amphetamines, Mixed

Amphetamine (amphetamine aspartate monohydrate, amphetamine sulfate), dextroamphetamine (dextroamphetamine saccharate, dextroamphetamine sulfate, D-amphetamine; Dexedrine); combination drug, mixed amphetamines: amphetamine and dextroamphetamine (Adderall; dexamphetamine).
Extraploated, based on similar properties: Methylphenidate (Metadate, Methylin, Ritalin, Ritalin-SR; Concerta); modafinil (Provigil), pemoline (Cylert).

The absorption of amphetamines in the gut can be increased by the acidification of the contents in the GI tract. Certain forms of ascorbic acid could theoretically alter the pH in the intestines and increase bioavailability, thus producing elevated drug levels.[286]

Pending substantive research findings, physicians prescribing mixed amphetamines may find it prudent to caution against unsupervised high-dose ascorbic acid intake, and advise patients to ingest vitamin C in supplemental form, and presumably acidic foods, at least 1 hour before or 2 hours after the medication.

Ampicillin, Related Beta-Lactam and Other Antibiotics

Evidence: Ampicillin (Amficot, Omnipen, Principen, Totacillin), aztreonam (Azactam injection), benzyl and procaine penicillin combination (Seclopen), cefotaxime (Claforan), gentamicin (G-mycin, Garamycin, Jenamicin); combination drug: sulfamethoxazole and trimethoprim (cotrimoxazole, co-trimoxazole, SXT, TMP-SMX, TMP-sulfa; Bactrim, Bactrim DS, Cotrim, Septra, Septra DS, Sulfatrim, Uroplus); streptomycin.
Similar properties but evidence indicating no or reduced interaction effects: Chloramphenicol (Chloromycetin).

Cephalosporins: Cefaclor (Ceclor), cefadroxil (Duricef), Cefamandole (Mandol), cefazolin (Ancef, Kefzol), cefdinir (Omnicef), cefepime (Maxipime), cefixime (Suprax), cefoperazone (Cefobid), cefotetan (Cefotan), cefoxitin (Mefoxin), cefpodoxime (Vantin), cefprozil (Cefzil), ceftazidime (Ceptaz, Fortaz, Tazicef, Tazidime), ceftibuten (Cedax), ceftizoxime (Cefizox), ceftriaxone (Rocephin), cefuroxime (Ceftin, Kefurox injection, Zinacef), cephalexin (Keflex, Keftab), cephapirin (Cefadyl), cephradine (Anspor, Velocef), loracarbef (Lorabid), meropenem (Merrem I.V.).

Clindamycin (Cleocin) and related lincosamide-class antibiotics.

Penicillins: Amoxicillin (Amoxil, Trimox); combination drugs: amoxicillin and clavulanate (Augmentin, Augmentin XR, Clavulin, Nuclav); ampicillin combination drug: ampicillin and sulbactam (Betamp, Unasyn), bacampicillin (Spectrobid); carbenicillin (Geocillin), combination drug: clavulanic acid and ticarcillin (Timentin); cloxacillin (Cloxapen), dicloxacillin (Dynapen, Dycill); imipenem combination drug: imipenem and cilastatin (Primaxin I.M., Primaxin I.V.); mezlocillin (Mezlin), nafcillin (Unipen), oxacillin (Bactocill), penicillin G (Bicillin C-R, Bicillin L-A, Pfizerpen), penicillin V (Beepen-VK, Veetids), piperacillin (Pipracil), piperacillin and tazobactam (Zosyn), ticarcillin (Ticar), ticarcillin and clavulanate (Timentin).
See also Tetracycline Antibiotics.

Alabi et al.[287] conducted in vitro experiments showing that a number of antibacterial agents may significantly reduce plasma levels of ascorbic acid: ampicillin, chloramphenicol, cefotaxime, gentamicin, benzyl and procaine penicillin combination (seclopen), co-trimoxazole, and streptomycin, in descending magnitude of effect.

Concomitant use of vitamin C could theoretically enhance antimicrobial activity and support immune response, but research is limited and findings have been preliminary. For example, Shoeb et al.[288] observed that "*Enterobacter cloacae* ATCC 13047 showed increasing susceptibility to ampicillin when incubated anaerobically in the presence of increasing concentrations of ascorbic acid." Under anaerobic growth conditions, "ascorbic acid abrogated the induction of the enzyme [beta-lactamase] completely. On the other hand, the constitutive enzymatic activity was markedly decreased as the bacterium was grown anaerobically."

A series of negative interactions were found by Belicova et al.,[288a] who conducted a series of in vitro experiments investigating effects of ascorbic acid on the antibacterial activity of selected antibiotics and synthetic chemotherapeutic agents by means of spectrophotometric measurements. They found that "ofloxacine, N-succinimidylofloxacine, fleroxacine, tetracycline, 6-thiatetracycline, and doxycycline reacted with ascorbic acid with the development of the superoxide radical (O_2^-)." Further, using Heatley's method, they demonstrated "that in the presence of ascorbic acid the antibacterial effect of substances was decreased by 9.6 to 40.7% and 10.1 to 45.1% in *Staphylococcus aureus* and *Escherichia coli*, respectively." In particular, they noted that "the kinetics of the process of the survival of cells within twenty-four hours demonstrated that a

combination of ofloxacine as well as tetracycline with ascorbic acid produced a statistically significant increase in log10 of CFU/ml in *S. aureus* as well as *E. coli*."

In contrast, Cursino et al.[289] subsequently documented a pattern of synergistic interaction between ascorbic acid (AA) and six antibiotics, in vitro, against 12 multidrug-resistant *Pseudomonas aeruginosa* isolates. They observed "synergic activity" with ascorbic acid and chloramphenicol, kanamycin, streptomycin, and tetracycline. "Indifference was observed to any antibiotics and antagonism only for chloramphenicol." The authors concluded that their findings "indicated that multiresistant *P. aeruginosa* was affected by combination of AA and antibiotics" and that continued "research on ascorbic acid–antimicrobial interactions may find new methods to control strains of multiresistant *P. aeruginosa*." The preliminary character and mixed findings of the available data indicate that further research is required before any well-founded conclusions can be made and clinical responses formulated.

Although specific survey data are unavailable, it seems highly probable that self-administration of vitamin C by patients undergoing treatment with antibiotics prescribed by physicians is relatively common practice in the United States, Europe, and elsewhere. The need for well-designed and adequately powered clinical trials investigating the safety and efficacy of such interactions and their permutations is imperative given such unsupervised coadministration. The uncertainties inherent in applying in vitro phenomena to in vivo clinical situations also suggest that placebo-controlled clinical trials involving patients with similar infections treated by the same antibiotics, informed by laboratory observations, would be necessary to formulate any clinically useful conclusions.

Governmental regulatory bodies, such as the U.K. Committee on Safety of Medicines (CSM), recommend that beta-lactam antibiotics be specifically reserved for treatment of verified bacterial infections associated with amoxicillin-resistant beta-lactamase–producing strains, and that treatment normally be limited to 14 days.

Anticonvulsant Medications, Including Phenytoin and Valproic Acid

Evidence: Carbamazepine (Carbatrol, Tegretol), divalproex semisodium, divalproex sodium (Depakote), primidone (Mysoline), sodium valproate (Depacon), valproate semisodium, valproic acid (Depakene, Depakene Syrup).
Extrapolated, based on similar properties: Clonazepam (Klonopin), clorazepate dipotassium (Tranxene), diazepam (Valium), ethosuximide (Zarontin), ethotoin (Peganone), felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), lamotrigine (Lamictal), levetiracetam (Keppra), mephenytoin, methsuximide (Celontin), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), phenobarbital (phenobarbitone; Luminol, Solfoton), phensuximide (Milontin), phenytoin (diphenylhydantoin; Dilantin, Phenytek), piracetam (Nootropyl), tiagabine (Gabitril), topiramate (Topamax), trimethadione (Tridione), vigabatrin (Sabril), zonisamide (Zonegran).

Primidone and other antiepileptic drugs (AEDs) may increase urinary excretion of ascorbic acid. Furthermore, the depleting effects of anticonvulsants on folate status could in turn adversely affect vitamin C status because ascorbic acid facilitates the conversion of folic acid to folinic acid, its active form.

Jurima-Romet et al.[290] conducted in vitro experiments demonstrating that vitamin C and vitamin E exerted a cytoprotective effect against 4-ene valproic acid–induced cytotoxicity in glutathione-depleted rat hepatocytes.

Secondary literature occasionally cites research indicating that concomitant use of barbiturates or primidone may increase urinary excretion of ascorbic acid, but substantive human research findings are lacking.[291]

Further research into the potential interaction between anticonvulsant medications and vitamin C is warranted. Pending substantive findings, physicians might find it prudent to prescribe vitamin C, at a modest dose level and with proper monitoring, to patients undergoing AED therapy.

The importance of folic acid during pregnancy is widely known, but equally important is the maintenance of sufficient levels of ascorbic acid and other antioxidant nutrients to prevent DNA damage. Such support is especially critical in women being treated with anticonvulsant therapy because of the drug-induced effects (e.g., reduction in plasma ascorbic acid, retinol, and beta-carotene levels) observed in nonsupplemented women on long-term AED therapy.

Clozapine and Related Atypical Antipsychotics

Clozapine (Chozaril).
Related but evidence lacking for extrapolation: Aripiprazole (Abilify, Abilitat), olanzapine (Symbyax, Zyprexa), quetiapine (Seroquel), risperidone (Risperdal), ziprasidone (Geodon).

Bioactivation of clozapine, a dibenzodiazepine antipsychotic, occurs in several tissues, including the liver, where it is catalyzed by the cytochrome (CYP) P450 enzymes, which results in the formation of both stable and protein-reactive metabolites. During hepatic metabolism of the piperazine ring, *N*-demethylation appears to be performed by CYP1A2, whereas *N*-oxidation and formation of chemically reactive metabolites depend on multiple forms of the CYP450 system.[292]

Agranulocytosis and hepatotoxicity are among the adverse effects uniquely associated with clozapine therapy. The unstable protein-reactive drug metabolites formed through bioactivation, particularly a nitrenium intermediate, have been implicated in this toxicity pattern. In the presence of a full hepatic enzyme-metabolizing system, both clozapine and demethylclozapine, a stable product, exhibit cytotoxicity toward polymorphonuclear leukocytes (PMNs) and mononuclear leukocytes. In contrast, clozapine *N*-oxide is not cytotoxic but is readily reduced (enzymatically) back to clozapine in the presence of NADPH; however, this conversion can be inhibited by ascorbic acid, probably by inhibiting the (unknown) reducing enzyme.[292,293] Further, fractions of the drug undergo covalent binding to microsomes and to protein in neutrophils and myeloid cells (drug-protein adducts).[294] Consequently, the action of these cytotoxic metabolites can inhibit the formation of neutrophils and stem cells, induce agranulocytosis, and cause abnormalities in the normal antioxidant defense system.[295]

Vitamin C (as well as glutathione and *N*-acetylcysteine) may block the adverse effects of these oxidative compounds and limit their damage to immune cells, most likely through their free-radical–scavenging activity. Further, because vitamin C can restore normal glutathione peroxidase levels, its presence can further enhance antioxidant protection. Intracellular reduced glutathione (GSH) is depleted with bioactivation of clozapine and demethylclozapine, but not clozapine *N*-oxide. In the presence of glutathione, clozapine glutathionyl adducts are formed as additional metabolites.[292] Thus, coadministration of ascorbic acid with clozapine may, directly and indirectly, reduce oxidative stress and prevent protein adduct formation.[293,296] However, the clinical implications of these in vitro findings have yet to be established.

In a cross-sectional pilot study, Linday et al.[295] found that patients with clozapine-induced agranulocytosis exhibited

lower levels of glutathione peroxidase, compared with controls, as well as evidence of free-radical–scavenging enzyme activity and levels of related trace metals. Levels of selenium, another important antioxidant, were lower in both groups of patients treated with clozapine, with and without agranulocytosis, than those of controls.

The mechanisms involved in adverse effects associated with bioactivation of clozapine have yet to be fully elucidated. Significant knowledge has emerged indicating the interrelated roles and implications of oxidation, free radicals, various clozapine metabolites and their respective effects, and the reversibility or irreversibility of reduction processes. However, these probable pathways have yet to be confirmed in humans. Further research through well-designed and adequately powered clinical trials are warranted to determine whether coadministration of vitamin C, alone or in combination with glutathione (most effective parenterally) and/or *N*-acetylcysteine (orally), can prevent, mitigate, or reverse adverse protein adduct formation, toxicity, and agranulocytosis. The low incidence of stark adverse effects of this nature suggests that genetic variability significantly influences the occurrence of a toxic response, and that assessment of pharmacogenomic risk factors may provide a useful tool for determining which patients are at higher risk and thus might be more likely to benefit from antioxidant support. The second- and third-generation atypical antipsychotics have different and milder adverse effect profiles than clozapine. Research such as that with clozapine is warranted with the other agents of this class.

Epinephrine

Epinephrine (Adrenaline, Epi; Adrenalin, Ana-Gard, AsthmaHaler, Asthma-Nefrin, Bronchaid, Bronkaid Mist, Brontin Mist, Epifin, Epinal, EpiPen, Epitrate, Eppy/N, Medihaler-Epi, Primatene Mist, S-2, Sus-Phrine; injectable: Adrenalin Chloride Solution, EpiPen Auto-Injector).

In an experiment involving healthy subjects, Cox et al.[297] observed that intravenous (IV) administration of epinephrine reduced plasma concentrations of vitamin C. The clinical implications of these findings for patients being treated with epinephrine are unknown at this time.

Further research through well-designed clinical trials may be warranted. Pending substantive findings, increased intake of vitamin C and related nutrients appears judicious in individuals using epinephrine on a regular or repeated basis.

Fenofibrate

Fenofibrate (Lofibra, Tricor, Triglide).

In one controlled human trial, Eberlein-Konig et al.[298] found that the combination of two grams of ascorbic acid and 1000 IU of d-alpha-tocopherol before ultraviolet exposure dramatically blocked ultraviolet phototoxic lysis of erythrocytes associated with fenofibrate. Pending further controlled human trials, these preliminary findings suggest that coadministration of ascorbic acid and vitamin E, preferably as naturally occurring tocopherols, might provide potential support to individuals undergoing fenofibrate therapy with minimal risk.

Haloperidol and Other Neuroleptic Agents

Haloperidol (Haldol)

Similar properties: Chlorpromazine (Largactil, Thorazine), clozapine (Clozaril), fluphenazine (Modecate, Permitil, Prolixin, Prolixin Decanoate, Prolixin Enanthate), olanzapine (Symbyax, Zyprexa), prochlorperazine (Compazine, Stemetil), quetiapine (Seroquel), risperidone (Risperdal).

See also Clozapine.

In relatively high systemic doses, ascorbate may exert an antidopaminergic action on striatal function, which mimics the pharmacology of haloperidol.[299,300]

Using a rodent model, Rebec et al.[301] observed that ascorbic acid (1000 mg/kg) alone failed to exert significant behavioral effects, but it "enhanced the antiamphetamine and cataleptogenic effects of haloperidol" (0.1 or 0.5 mg/kg), compared with saline. Subsequently, Pierce, Rebec, et al.[299] found that the combination of ascorbate (100 or 500 mg/kg) over 21 days can potentiate the effects of chronic haloperidol (0.5 mg/kg) on behavioral supersensitivity to apomorphine, but did not affect striatal dopamine (D_2) receptor binding. These researchers concluded that "these findings indicate that although chronic ascorbate produces behavioral supersensitivity to apomorphine through central mechanisms, they appear to differ from those induced by chronic haloperidol." In a related experiment, they found that "repeated treatment with ascorbate or haloperidol, but not clozapine, elevates extracellular ascorbate in the neostriatum of freely moving rats."[302] Finally, Gulley and Rebec[300] demonstrated a modulatory effect of ascorbate (100 and 1000 mg/kg intraperitoneally), alone or with haloperidol (0.01 and 0.05 mg/kg subcutaneously), on a lever-release conditioned avoidance response task in male rats. They interpreted the observed contrast between increase in avoidance latency and the lack of effect on conditioned avoidance response when the two agents were coadministered as indicating "an antidopaminergic action of ascorbate on striatal function, but suggest that this effect requires relatively high systemic doses."

However, in a 2-week open trial, Straw et al.[303] administered oral doses of ascorbic acid, 4.5 g daily, to eight male inpatients diagnosed with chronic schizophrenia and stabilized on a fixed dose of haloperidol. They reported no significant clinical change in psychopathology in these subjects, nor any apparent pharmacokinetic interaction with haloperidol, associated with the addition of ascorbic acid.

Although lacking evidence from adequately powered clinical trials, these collective findings suggest a potential dose-dependent synergistic interaction between ascorbate and haloperidol. Further research may be warranted. In the meantime, patients should be advised to avoid such concomitant usage without first discussing such practices with their prescribing physician. Monitoring and supervision are appropriate in individuals using both agents.

Heparin, Unfractionated; Low-Molecular-Weight Heparin

Heparin, unfractionated (UFH): Heparin (Calciparine, Hepalean, Heparin Leo, Minihep Calcium, Minihep, Monoparin Calcium, Monoparin, Multiparin, Pump-Hep, Unihep, Uniparin Calcium, Uniparin Forte).

Low-molecular-weight heparin (LMWH): Ardeparin (Normiflo), certoparin (Mono-Embolex), enoxaparin (Clexane, Lovenox), dalteparin (Fragmin), nadroparin (Fraxiparine), tinzaparin (Innohep).

Similar properties but evidence lacking for extrapolation: Argatroban, bivalirudin (Angiomax), dabigatran etexilate (Rendix; investigational), danaparoid (Orgaran), desirudin (Iprivask, Revasc), fondparinux (Arixtra), hirudin, lepirudin (Refludan).

The preliminary discussion of potential heparin–ascorbic acid antagonism by Owen et al.[304] in 1970 never lead to substantive research.

The integrity of heparin, in both forms (UFH, LMWH), can be adversely affected by oxidative stress, such as that

resulting from iron, copper, peroxidases, and other sources of free radicals, although LMWH may be less susceptible than UFH because of its uniform shorter chain length and the significantly less nonspecific binding required to inactivate it.[305-307] Consequently, coadministration of antioxidant nutrients including vitamin C may protect heparin and enable it to maintain its therapeutic activity. In several studies, Deepa and Varalakshmi[308-313] have investigated the cytoprotective activity and beneficial effect of LMWH on cardiac, hepatic, and renal lipid peroxidation and collapse of antioxidant defenses resulting from gentamicin-induced glomerulotoxicity, adriamycin-induced cardiac and hepatic toxicity, atherogenic diet, oxalate-mediated lithogenesis, and other stressors.[314] These and related findings indicate that further investigation into the clinical implications of potential synergy among heparin, ascorbic acid, and other antioxidant nutrients is warranted.

Indomethacin and Related Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Evidence: Indomethacin (indometacin; Indocin, Indocin-SR).
Similar properties but evidence lacking for extrapolation
COX-1 inhibitors: Diclofenac (Cataflam, Voltaren); combination drug: diclofenac and misoprostol (Arthrotec); diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), furbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen; combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen), ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).
COX-2 inhibitors: Celecoxib (Celebrex).
See also Acetaminophen and Acetylsalicylic Acid (Aspirin) and Salsalate sections.

Several small and preliminary studies directly and indirectly indicate patterns of interaction between vitamin C and specific NSAID drugs. However, evidence is lacking from in-depth and focused research on particular interactions and their clinical implications. Potential issues involve synergistic or additive anti-inflammatory activity, impairment of normal nutrient physiological activity, and drug-induced nutrient depletion. The limited evidence available does not suggest a significant risk of impairment of drug therapeutic activity by vitamin C, although any conclusions, especially generalizations for the drug class as a whole, would be speculative.

In a small study on airway tone in the basal state in six healthy, nonsmoking male adults, Ogilvy et al.[314a] investigated the effects of ascorbic acid and indomethacin. Neither ascorbic acid (1.0 g orally) nor indomethacin (50 mg orally) alone produced a significant change in measurements assessing basal tone. However, the researchers noted that "both the duration and intensity of the bronchoconstriction induced by methacholine aerosol (10 mg/mL for 30 sec) were significantly reduced by prior administration of ascorbic acid," but that this "ameliorating action of ascorbic acid was blocked by ingestion of indomethacin." They interpreted their primary findings as suggesting that "ascorbic acid exerts its effects by altering the production of a bronchodilator prostaglandin."

In a double-blind, randomized, crossover study involving 14 healthy volunteers, McAlindon et al.[56] administered aspirin (900 mg twice daily) and placebo, allopurinol (100 mg twice daily), sulfasalazine (1 g twice daily), or vitamin C (1 g twice daily) for 3 days to assess gastric mucosal reactive oxygen metabolite release and gastroduodenal injury. They found that no agent "reduced any parameter of gastric injury but vitamin C reduced duodenal injury assessed by Lanza score," and concluded that vitamin C had demonstrated a previously unrecognized protective effect against aspirin-induced duodenal injury.

The limited data available regarding interactions between NSAIDs and vitamin C suggest that further research is warranted, especially given the high incidence of use, prescribed and self-administered, of these agents.

Isoniazid and Related Antitubercular Agents

Evidence: Isoniazid (isonicotinic acid hydrazide; INH, Laniazid, Nydrazid).
Related but evidence lacking for extrapolation: Cycloserine (Seromycin), ethambutol (Myambutol), ethionamide (2-ethylthioisonicotinamide; Ethide, Ethiocid, Ethomid, Etomide, Mycotuf, Myobid, Trecator SC), pyrazinamide (PZA; Tebrazid), rifampicin (Rifadin, Rifadin IV); combination drugs: isoniazid and rifampicin (Rifamate, Rimactane); isoniazid, pyrazinamide, and rifampicin (Rifater).

Isoniazid (INH) and its metabolites, particularly hydrazine, are known to cause formation of the free-radical intermediates and are thus suspected as the source of INH-induced hepatic injury. The hydrazyl radical alpha-(4-pyridyl-1-oxide)-*N*-tert-butylnitrone (4-POBN), one of these toxic intermediates, appears to be formed by the CYP450-dependent microsome systems. The antioxidant activity of ascorbic acid may mitigate such oxidative damage.

In an in vitro experiment using electron spin resonance (ESR) spectroscopy and spin-trapping technique, Matsuki et al.[314b] generated findings indicating that hydrazine (Hy) was "most intensive" among the free-radical intermediates formed by isoniazid (INAH) and its metabolites and likely to be a "potent intermediate" involved in INAH-induced hepatic injury. "In the presence of ascorbic acid (AA), the free radical formation of Hy, INAH and acetyl hydrazine was significantly inhibited, suggesting that AA may affect the INAH-hepatitis." They confirmed that "the radical is formed by the cytochrome P-450 dependent microsome systems" when they observed a decrease in the generation of the radical from hydrazine on the addition of CYP450 inhibitors.

These preliminary findings suggest that coadministration of vitamin C, preferably as part of a multinutrient-antioxidant network, might prevent or reduce drug toxicity effects resulting from free-radical damage associated with isoniazid and other antituberculotic medications. Further research into potential protective effects of concomitant antioxidant support, particularly compatibility, dosage, and timing, may be warranted.

Mexiletine

Mexiletine (Mexitil).

Doses of ascorbic acid greater than 1 g daily have been reported to accelerate the excretion of the antiarrhythmic drug mexiletine. The clinical significance of this is unclear.

Mexiletine has also been found to possess antioxidant activity in brain membranes, although at millimolar concentration, significantly less potent than vitamin C and most antioxidant nutrients.[315]

Pending substantive research findings, physicians prescribing mexiletine for ventricular arrhythmias should caution patients to use vitamin C in supplemental form at levels of 1 g daily or higher only with medical supervision and appropriate monitoring.

Phenothiazines

Evidence: Fluphenazine (Modecate, Permitil, Prolixin, Prolixin Decanoate, Prolixin Enanthate), perphenazine (Trilafon), thioridazine (Mellaril).
Extrapolated: Acetophenazine (Tindal), chlorpromazine (Largactil, Thorazine), mesoridazine (Serentil), methotrimeprazine (levomepromazine; Nozinan), pericyazine (Neuleptil); perphenazine combination drug: perphenazine and amitriptyline (Etrafon, Triavil, Triptazine); prochlorperazine (Compazine, Stemetil), promazine (Sparine), promethazine (Phenergan, Promacot, Promethegan), propiomazine (Largon), thiethylperazine (Torecan), thioproperazine (Majeptil), trifluoperazine (Stelazine), triflupromazine (Vesprin).

Hoffer, VanderKamp, Smythies, and others have discussed metabolic abnormalities involving ascorbic acid as potential contributors in the etiology of schizophrenia and other forms of mental illness. Such assertions remain contentious within conventional medicine, with no agreement on mechanisms of action and a lack of evidence from well-designed and adequately powered clinical trials.

Beauclair et al.[316] stated that 8 of 10 schizophrenic subjects in an uncontrolled trial reported decreases in disorganized thoughts, hallucinations, and paranoia when ascorbic acid (8 g/day) was added to their standard drug therapy.

Dysken et al.[316a] described a male patient with a history of manic behavior whose serum fluphenazine levels decreased by 25% (from 0.93 to 0.705 ng/mL) and whose clinical condition greatly deteriorated over 13 days during which 500 mg ascorbic acid was taken twice daily.

Amenorrhea occurs in many female patients undergoing treatment with phenothiazines. In one clinical anecdote, Kanofsky et al.[317] described a 45-year-old woman taking thioridazine who resumed menstruating after initiating daily intake of 6 g of ascorbic acid.

No substantive body of qualified evidence or clear pattern of interaction is present in these inconsistent data. Consequently, the question of whether a clinically significant interaction occurs with known probability cannot be answered at this time. Given the absence of a predictable generalized pattern of interaction, the medical condition of a given patient, their pharmacognomic individuality, concomitant medication regimen, and nutritional status all play potentially significant roles. Caution, close supervision, and regular monitoring are essential if acscorbic acid, in pharmacological doses, and a phenothiazine drug are used concomitantly. Controlled clinical trials may be warranted to determine the safety and efficacy of coadministration of vitamin C and neuroleptic agents.

Probenecid

Probenicid (Benemid, Probalan).

Probenecid increases excretion of uric acid and is used to treat patients with gout. Vitamin C can also increase uric acid excretion and has been administered in graduated doses to treat gout. However, concerns have been voiced that high ascorbate intake might precipitate an acute gouty episode in some individuals, based on possible changes in uric acid solubility within joint spaces. The concomitant administration of probenecid and ascorbic acid, under professional supervision, could theoretically enhance the therapeutic efficacy of gout therapy, but substantive evidence from human research is lacking. Controlled trials may be warranted.

Selective Serotonin Reuptake Inhibitor (SSRI) Antidepressants

Evidence: Fluvoxamine (Faurin, Luvox); paroxetine (Aropax, Deroxat, Paxil, Seroxat).
Extrapolated, based on similar properties: Citalopram (Celexa), escitalopram (S-citalopram; Lexapro), fluoxetine (Prozac, Seraphim), sertraline (Zoloft).

Limited data from a published case report suggest that vitamin C might reduce bleeding associated with paroxetine and fluvoxamine.[318]

Tacrine

Tacrine (Tetrahydroaminoacridine, THA; Cognex).

Hepatotoxicity resulting in irreversible liver damage is a known adverse effect associated with tacrine. Research indicates that, in the course of bioactivation, tacrine undergoes "extensive oxidative metabolism to a variety of mono- and dihydroxylated metabolites in animals and humans."[319] Limited evidence from in vitro experiments using human and rat liver microsomes suggests that concomitant intake of ascorbic acid might inhibit the formation of cytotoxic metabolites from tacrine. In particular, researchers found that reduced glutathione (500 μM) "completely blocked NADPH-dependent cytotoxicity and inhibited protein-reactive metabolite formation by 60%," and "ascorbic acid (500 μM) inhibited the generation of cytotoxic and protein-reactive metabolites" by 75% and 35%, respectively.[319]

Clinical trials may be warranted to investigate potential hepatoprotective activity from coadminsitration of ascorbic acid during tacrine therapy.

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Warfarin (Coumadin, Marevan, Warfilone).
Extrapolated, based on similar properties: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar).

Data from some, but not all, animal experiments and rare, unqualified case reports indicates that vitamin C, in high doses, might decrease functional levels and therapeutic activity of warfarin, but the cumulative body of evidence fails to support a well-founded, consistent, and generalizable conclusion.[320-325] Reports of lowered prothrombin time (PT) in individuals taking large doses of vitamin C, outside of professional supervision, have not lead to confirmation of clinically significant complications (e.g., increased clotting), nor has awareness of such potential resulted in substantial reports of any broader patterns or frequency of occurrence. The actual occurrence and clinical implications of a potential interaction remain controversial, and most probably derive from individual patient characteristics, warfarin tolerance and other pharmacogenomic variability, dose factors and regularity of drug-nutrient intake, dietary factors, concomitant medications, and comorbid pathologies.

No generally agreed-on or well-supported mechanism of action has emerged to confirm or explain an interaction between vitamin C and warfarin or related anticoagulants. After declaring the mechanism involved as "not understood," Stockley[239] suggests that decreased warfarin bioavailability resulting from diarrhea induced by high-dose ascorbic acid may be a factor in reported but inconsistent and unpredictable alterations in warfarin levels and therapeutic activity.

Isolated case reports involving uncoordinated ascorbic acid self-administration from the early 1970s form the foundation

of speculative claims that ascorbic acid can adversely affect warfarin kinetics and impair therapeutic activity.[325] In a published letter, Rosenthal[326] described the case of a woman, stabilized on 7.5 mg warfarin daily, in whom initiation of regular intake of ascorbic acid (at an unstated dose) was associated with a steady decline in PT from 23 seconds to 19, 17, and then 14 seconds; further, the patient failed to respond to an increase in the dosage of warfarin to 10, 25, and eventually 20 mg per day. This patient returned to PT of 28 seconds within 2 days of halting ascorbic acid supplementation. Smith et al.[327] reported the case of a female patient who exhibited warfarin resistance while taking self-prescribed vitamin C at 16 g/day. A significant increase in PT was obtained after increasing her warfarin dose to 25 mg/day.

Findings from the four controlled trials involving large numbers of subjects indicate a lack of clinically significant interaction between warfarin and ascorbic acid, even at doses as high as 10 g vitamin C per day. Hume et al.[328] observed no significant alterations in anticoagulant effects in five warfarin-treated patients administered 1 g ascorbic acid daily for a 2-week period. Similarly in a trial involving 84 patients on chronic anticoagulant therapy, Dedichen[329] reported no observable effects after administration of an unstated amount of ascorbic acid for 10 weeks. In a study involving 19 patients administered ascorbic acid at doses up to 5 to 10 g daily for 1 or 2 weeks, Feetam et al.[330] observed a mean fall of 17.5% in total plasma warfarin concentrations but reported no "clinically important interaction," as demonstrated by changes in medication effects. Likewise, Blakely[331] reported an absence of clinically significant alteration in warfarin activity in 11 patients administered up to 4 g ascorbic acid daily for 2 weeks.

Physicians prescribing warfarin or related anticoagulant medications are advised to obtain an inventory of both regularly and occasionally used supplements and caution patients against initiating or abruptly changing dosage levels of vitamin C or other nutrients (or herbs) without proper professional supervision and increased monitoring of INR and other relevant hematological parameters. Even with cautious acknowledgment of the available reports, tentative and inconsistent as they are, it is improbable that a clinically significant interaction might occur, in most individuals, at doses less than 1 g daily. Thus, Stockley[239] concluded: "There is no good reason for avoiding the concurrent use." Nevertheless, as always, regular monitoring and repeated inquiry, as well as concern for warfarin resistance, are essential in managing patients undergoing anticoagulant therapy.

NUTRIENT-NUTRIENT INTERACTIONS

Alpha-Lipoic Acid

Alpha-lipoic acid and vitamin C both possess significant antioxidant properties and, as such, demonstrate synergistic activities against free radicals. In general, antioxidant agents function most effectively, and with the least risk of shifting into pro-oxidant activity, when used in clusters to create the effect of an antioxidant network.[332,333] Although widespread and growing scientific research into the physiological activities and therapeutic implications of antioxidants remains largely preliminary, with the well-designed, large, long-term French SU.VI.MAX (Supplementation en Vitamines et Mineraux Antioxydants) prospective study being the significant exception.[334] Diabetic neuropathies and ocular diseases are among the most prominent of numerous areas of clinical importance, which are the subjects of ongoing and anticipated research into potential synergies between vitamin C and alpha-lipoic acid.[335,336]

The interdependent relationships and biochemical interactions among vitamin C, alpha-lipoic acid, and other antioxidants, particularly vitamin E, demonstrate important aspects of the model of antioxidant networks, their physiological activities, and clinical implications. Alpha-lipoic acid demonstrates significant antioxidant activities by deactivation of reactive oxygen and nitrogen species, both in vivo and in vitro. Furthermore, dihydrolipoic acid may act as a "strong direct chain-breaking antioxidant" and enhance the antioxidant potency of ascorbate and vitamin E. In 1992, Kagan et al.[337] found that dihydrolipoic acid (but not thioctic acid, its oxidized form) "reduced ascorbyl radicals (and dehydroascorbate) generated in the course of ascorbate oxidation by chromanoxyl radicals. This interaction resulted in ascorbate-mediated dihydrolipoic acid–dependent reduction of the vitamin E chromanoxyl radicals, i.e. vitamin E recycling." Casciari et al.[13] found that "ascorbate increased the percentage of apoptotic cells in SW620 hollow fibre tumours" and that coadministration of lipoic acid "synergistically enhanced [this] ascorbate cytotoxicity." Furthermore, lipoic acid, "unlike ascorbate, was equally effective against proliferating and non-proliferating cells." Lu and Liu[338] investigated the synergistic interaction of lipoic acid with other endogenous and exogenous antioxidants. They found that vitamin C, as well as Trolox (a water-soluble derivative of alpha-tocopherol) and hydroxycinnamic acid derivatives, were able to "recycle lipoic acid by donating electrons to lipoic acid radical cations, thereby increasing the antioxidant capacity of lipoic acid *in vivo* and *in vitro*."

Bioflavonoids

Bioflavonoids and vitamin C often function synergistically, as might be expected from their frequent presence together in many foods. Simultaneous oral intake with bioflavonoids can enhance bioavailability of vitamin C.[339] Bioflavonoids perform antioxidant functions in concert, and ascorbic acid can protect flavonoids from oxidative degradation.[340]

Copper

Limited evidence suggests that vitamin C intake, at greater than 1 g/day, may reduce copper retention and contribute to copper depletion. Copper absorption may theoretically be impaired by concomitant high ascorbic acid intake, possibly resulting in lowered ceruloplasmin levels, but conclusive evidence is lacking to confirm a pattern of clinically significant interaction.

Finley and Cerklewski[341] investigated the influence of ascorbic acid supplementation on copper status in an experiment involving young adult men consuming self-selected diets and administered 500 mg of ascorbic acid with each meal (1500 mg/day) for 64 days. "Each subject thus served as his own control." They observed that serum ceruloplasmin activity was "significantly reduced . . . at every data point throughout the ascorbic acid supplementation period," and that a "similar but nonsignificant trend was observed for serum copper. Furthermore there was a significant increase . . . in serum copper concentration 20 days after the supplementation period." Although these observed effects "occurred within physiological ranges of normal values, this study confirms that a high ascorbic acid intake is antagonistic to copper status of men, as has been demonstrated in laboratory animals." Subsequently, Jacob et al.[342] conducted a study of

intestinal copper absorption and blood measures of copper status in healthy young men receiving varying intakes of ascorbic acid over 14 weeks using a live-in nutrition suite. Using "both enzymatic and immunochemical methods," they observed that copper "absorption, copper retention, total serum copper and the serum level of ceruloplasmin protein were not affected significantly by the changes" in ascorbic acid (AA) intake, but that the "oxidase activity of serum ceruloplasmin was decreased an average of 21% during the high (605 mg/d)" AA intake phase. The authors interpreted their findings as suggesting that "in adult men moderate supplemental intakes of AA reduce ceruloplasmin oxidase activity specifically but do not depress intestinal copper absorption or overall body copper status." Notably, the levels of ascorbic acid administered in this latter study were about one-third those used in the former study.

Folic Acid

Vitamin C appears to play an important role in the activation of folic acid to form folinic acid, possibly by acting as a reducing agent. Well-founded conclusions are as yet premature because data from primary scientific literature are inconclusive, and secondary discussions are conflicting in their interpretations.

Glutathione (GSH)

Unlike most mammals, which are able to synthesize ascorbic acid in the liver, humans and guinea pigs possess no ability to synthesize ascorbate de novo. In particular, hepatic glutathione plays an essential role in regeneration of vitamin C. During in vitro experiments using serum albumin from rats, Vethanayagam et al.[343] observed that albumin "acts as an antioxidant and exerts a significant glutathione-dependent DHAA-reductase activity that may be important in the physiologic recycling of ascorbic acid" from dehydroascorbate (DHAA), its oxidized byproduct. Likewise, using cultured liver-derived cells from humans (HepG2 cells) and rats (H4IIE cells) Li, May, et al.[344] confirmed that GSH is required to recycle ascorbic acid. They noted that in "both cell types, DHA [dehydroascorbic acid] reduction lowered glutathione (GSH) concentrations and was inhibited by prior depletion of GSH" and concluded that "both cell types rely largely on GSH- or NADPH-dependent mechanisms for ascorbate recycling from DHA." These researchers also found that GSH is required for recycling of ascorbic acid in endothelial cells.[345] Subsequently, using a mouse model, Gao et al.[346] demonstrated "enhancement of glutathione cardioprotection by ascorbic acid in myocardial reperfusion injury."

Consistent with the antioxidant network model, coadministration of these two antioxidants can be reasonably expected to synergistically enhance the activity of both agents. Glutathione levels can be positively influenced by parenteral glutathione (prepared by compounding pharmacies), oral liposomal glutathione, oral supplements of *N*-acetylcysteine, and whey-derived cysteine peptide supplementation.

Grape Seed Extract

In a randomized, double-blind, placebo-controlled trial, Ward et al.[347] investigated the effects of coadministration of vitamin C and grape seed polyphenols in 69 individuals being treated for hypertension. The participants received 500 mg/day vitamin C, 1000 mg/day grape seed polyphenols, both vitamin C and polyphenols, or neither for 6 weeks. Vitamin C alone reduced systolic blood pressure (BP, vs. placebo), whereas no effect was observed with polyphenols. However, these investigators reported a "significant interaction between grape-seed and vitamin C treatments" in which systolic BP and diastolic BP increased 4.8 ± 0.9 mm Hg and 2.7 ± 0.6 mm Hg, respectively (vs. placebo). Notably, "endothelium-dependent and independent vasodilation, and markers of oxidative damage were not significantly altered." The authors added that, although the mechanism underlying these phenomena "remains to be elucidated," these results "suggest caution for hypertensive subjects taking supplements containing combinations of vitamin C and polyphenols." Further research appears warranted to confirm and determine the frequency, characteristics, and clinical significance of this possible interaction.

Iron

Vitamin C, in supplements or vitamin C–rich foods, can strongly enhance the absorption of nonheme iron in the GI tract by reducing dietary ferric iron (Fe^{3+}) to ferrous iron (Fe^{2+}), forming a highly absorbable iron-ascorbic acid complex, and increasing bioavailability of the iron twofold to threefold.[239,348-352] Levine et al.[12] reported that concomitant intake of vitamin C at 200 mg/30 mg elemental iron increases iron absorption, especially ferric iron.[12] This effect, however, apparently is influenced by gastric pH, bile function, and other dietary constituents; is highly dose dependent; and is relatively minor at ascorbic acid doses under 200 mg, even in individuals with low iron stores.[349,353,354]

However, ascorbic acid can prevent the dose-dependent inhibitory effects of polyphenols and phytates on nonheme-iron absorption.[355] Furthermore, ascorbate stabilizes the iron cores of ferritin in cells and retards ferritin degradation and autophagic uptake of ferritin clusters into lysosomes.[356]

Iron deficiency anemia affects one third to half of children in the developing world. Zlotkin et al.[357] found that adding "sprinkles" (ferrous fumarate and ascorbic acid microencapsulated in a thin, soy-based coat) to weaning foods can be an effective tool in reducing rates of anemia in susceptible children.

The two primary risks potentially attributed to the combined influence of iron and ascorbic acid are iron overload and increased oxidative stress. (See earlier erythropoietin section for a discussion of these issues in that context.)

Overall, the probability of iron overload from concomitant intake of iron and vitamin C is extremely low in individuals without transfusion or IV iron–produced iron overload or genetic hemochromotosis. However, the risk of an adverse interaction is significant in individuals with genetic hemochromatosis, which remains asymptomatic until late stages of iron overload, and iron intake should absolutely be restricted in such patients. A transferrin saturation of greater than 70% should trigger high suspicion of hemachromatosis and further investigation.

Limited in vitro evidence has suggested that concomitant iron and ascorbic acid might result in a paradoxical pro-oxidant effect within the context of high oxidative stress, but human trials have failed to confirm such findings. In a study involving 40 healthy female and male volunteers, Proteggente et al.[358] investigated the potential for a pro-oxidant interaction of iron and ascorbate by testing the effects of iron supplementation on oxidative damage to DNA. Subjects "with plasma ascorbate levels at the upper end of the normal range (mean plasma ascorbate approximately equal to 70 micromol/L)" were "supplemented with a daily dose of syrup (ferrous glycine sulphate equivalent to 12.5 mg iron)" over 6 weeks. After assessing a number of relevant parameters in serum and

plasma samples, including serum ferritin, transferrin-bound iron, percent saturation of transferrin and plasma ascorbate, and measurement of oxidative damage to DNA bases from WBCs using gas chromatography/mass spectrometry, they determined that "iron supplementation did not affect any of the iron status parameters," and that there were "no detrimental effects, over the period under investigation, in terms of oxidative damage to DNA." The authors cautioned, however, that "the effects of larger doses or of longer supplementation periods should also be investigated."[358] A dose of 12.5 mg iron is below the daily value (DV) for most population groups and far below therapeutic doses used to correct iron deficiency states.

Lutein

The mutual occurrence of high levels of both lutein and vitamin C in some plants suggests a potential synergistic relationship between these two antioxidant nutrients. Carotenoids are lipophilic and hydrophobic, and absorption is enhanced by dietary fat. In an experiment involving nine young adults, however, Tanumihardjo et al.[359] found that simultaneous administration of ascorbic acid facilitated lutein absorption.

Selenium

The relationship between ascorbic acid and selenium is complex and only partially understood. The allied roles of these nutrients are well established, particularly with regard to the activity of glutathione peroxidase, and often relied on in clinical application of antioxidants. For example, among the numerous selenium-dependent enzymes, also known as *selenoproteins*, thioredoxin reductase maintains the antioxidant function of vitamin C by catalyzing its regeneration.[360] However, other evidence derived from short-term human experiments investigating the interaction between dietary ascorbic acid at extremes of intake and selenium (Se) in young adult males indicates that doses of vitamin C greater than 1 g may reduce the absorption of selenium. Nevertheless, the authors concluded that these "data and those previously obtained in subjects with more usual ascorbic acid intakes point to a possible important role for ascorbic acid in the maintenance of Se homeostasis."[361] Pending more conclusive evidence, prudence suggests that selenium be ingested 1 hour before or 20 minutes after taking vitamin C.

Taurine

In an animal experiment, Mochizuki et al.[362] reported an "amplifying effect of dietary taurine on the induction of cytochrome P-450 and on the urinary excretion of ascorbic acid in rats fed on phenobarbital-containing diets." Such observations suggest the potential for clinically significant implications involving both medications and xenobiotics metabolized by hepatic cytochrome P450 enzymes and thus indicate that further research is warranted.

Vitamin B_6

Urinary excretion of pyridoxine may be increased in individuals with vitamin C deficiency. Conversely, rare individuals may develop profound hyperoxaluria in response to supraphysiological intake of vitamin C, which could increase risk of renal oxalate calculi. In such individuals, pyridoxine in doses of 100 to 300 mg per day (often in conjunction with magnesium supplementation) has been shown to normalize the oxalate production and excretion.

Vitamin B_{12}

Some sources suggest that vitamin C may damage or diminish the effectiveness of vitamin B_{12} if taken together. This potential interaction may be prevented by not taking large doses of vitamin C within 1 hour of oral vitamin B_{12} intake.

Vitamin E

Vitamin C facilitates regeneration of vitamin E and restoration of its antioxidant activity, thus providing an excellent example of an effective antioxidant network. Their strong presence in diets rich in vegetables and fruits associated with reduced risk of cardiovascular disease and cancer suggests that coadministration may be beneficial. Regarding their role in secondary cardiovascular prevention, Gey[78] concluded that "vitamin E acts as first risk discriminator, vitamin C as second one; optimal health requires synchronously optimized vitamins C + E, A, carotenoids and vegetable conutrients."

Zandi et al.[363] examined data from the Cache County Study, a large, population-based investigation of the prevalence and incidence of Alzheimer's disease and other dementias, and determined that regular use of vitamin E in nutritional supplement doses, especially in combination with vitamin C, may protect the aging brain against pathological changes associated with Alzheimer's disease and reduce the risk of developing the condition. Further study with randomized prevention trials is needed before drawing firm conclusions about the protective effects of such coordinated antioxidant supplementation. If effective, the use of these (and possibly other) antioxidant nutrients may offer a safe and inexpensive strategy for reducing the risk of developing Alzheimer's dementia.

Bruno et al.[364,365] have conducted extensive research into the relationship between vitamin C and alpha-tocopherol, with a focus on the conditions of high oxidative stress found in smokers. First, they found that vitamin E disappearance "is accelerated in cigarette smokers due to their increased oxidative stress and is inversely correlated with plasma vitamin C concentrations."[364] Then, in a double-blind, placebo-controlled, randomized crossover trial, they demonstrated that ascorbic acid (500 mg twice daily for weeks) doubled "plasma ascorbic acid concentrations in both groups and attenuated smokers', but not nonsmokers', plasma alpha- and gamma-tocopherol . . . fractional disappearance rates by 25% and 45%, respectively. Likewise, smokers' plasma deuterium-labeled alpha- and gamma-tocopherol concentrations were significantly higher . . . at 72 h during ascorbic acid supplementation compared with placebo." They concluded that "cigarette smoking increased plasma alpha- and gamma-tocopherol fractional disappearance rates, suggesting that the oxidative stress from smoking oxidizes tocopherols, and that plasma ascorbic acid reduces alpha- and gamma-tocopherol radicals to nonoxidized forms, thereby decreasing vitamin E disappearance in humans."[365]

Vitamin K

In 1952, Merkel[366] found that coadministration of menadione bisulfite (vitamin K_3 sodium bisulfite, which lacks vitamin K activity until metabolized to menaquinone, also known as vitamin K_2) and ascorbate provided complete relief of symptoms within 3 days in 64 of 70 consecutive cases of nausea and vomiting of pregnancy. These findings have not been followed up.

Vitamin K_3 combined with IV ascorbate has shown recent promise as an oxidative therapy for cancer. Similar preliminary

studies have involved use of K_5 in conjunction with IV and oral ascorbate. Vitamin K_3 is a more active free-radical generator than is K_2.[367-371]

HERB-NUTRIENT INTERACTION

Reishi Mushroom (*Ganoderma lucidum*)

Futrakul et al.[372] found that coadministration of vitamins C and E along with *Ganoderma lucidum* as a treatment for steroid-resistant nephrosis "helps to neutralize oxidative stress and suppress the toxic effect to the glomerular endothelial function."

The 380 citations for this monograph, as well as additional reference literature, are located under Vitamin C (Ascorbic Acid) on the CD at the back of the book.

Vitamin D (Calciferol)

Nutrient Names: Vitamin D, calciferol.
Synonyms: 1,25-Dihydroxyvitamin D, calciferol, calcipotriol, cholecalciferol (vitamin D_3), ergocalciferol (vitamin D_2), irradiated ergocalciferol, ergosterol (provitamin D_2), activated/irradiated ergosterol (vitamin D_2).
Related Substance: Calcitriol is also the name of a drug that is the active (1,25-dihydroxycholecalciferol) form of vitamin D.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Allopurinol ⊕⊕	Allopurinol may elevate serum concentrations of $1,25(OH)_2$-vitamin D_3 by reducing uric acid's inhibition of 1-hydroxylase activity.	Assess vitamin D status. Allopurinol may increase $1,25(OH)_2D$ levels, especially with supplementation.
Androgen-deprivation therapy (ADT) ☼/⊕⊕	Concomitant vitamin D and calcium can counter skeletal impact of deficiency patterns associated with prostate cancer treatment, decreased sex hormone levels, and ADT, especially when used with bisphosphonates. Consensus of evidence is emerging for this clinically significant, supportive interaction, as are clinical guidelines.	Coadminister vitamin D and calcium and monitor bone and D status. Promote sunlight exposure and exercise.
Anticonvulsant medications ≈≈≈/◈/☼	Phenytoin and phenobarbital accelerate vitamin D metabolism in liver (CYP450 induction) and may reduce serum levels of 25(OH)D. Thus, anticonvulsants may impair mineralization, leading to increased risk of bone loss, osteoporosis, osteomalacia, rickets, and fractures. Coadministration of "high-dose" vitamin D can mitigate drug-induced vitamin D depletion and related bone loss.	Coadminister vitamin D and calcium. Monitor serum 25-OHD and bone status. Promote sunlight exposure and weight-bearing exercise.
Bisphosphonates ⊕⊕⊕	Synergistic interaction; vitamin D assists calcium absorption, and both enable bisphosphonates in maintaining bone mineralization, including with hormone replacement therapy (HRT).	Coadminister vitamin D; administer calcium but separate intake from bisphosphonates. Promote appropriate sunlight exposure and weight-bearing exercise.
Calcitriol Vitamin D analogs ✗✗/✗✗✗/◈◈	Additive effect from concurrent use would increase risk of vitamin D toxicity, especially since $1,25(OH)_2D$ and analogs bypass renal feedback controls.	Caution; generally avoid. Possible value in coadministration (e.g., renal disease) with monitoring.
Cholestyramine Colestipol Bile acid sequestrants ≈≈≈/◈	Bile acid sequestrants decrease lipid digestion and absorption and thereby reduce absorption of vitamin D and fat-soluble nutrients. Risk of deficiency and sequelae.	Supplement vitamin D. Promote sunlight exposure and weight-bearing exercise.
Cimetidine Histamine (H_2) receptor antagonists ≈≈≈/◈	Cimetidine may inhibit action of vitamin D hydroxylase and could reduce hepatic activation of vitamin D through hydroxylation. Possible risk of deficiency.	Monitor 25(OH)D. Compensatory supplementation may be appropriate.
Corticosteroids, oral ≈≈≈/◈≈≈/◈	Oral corticosteroids reduce calcium absorption and may increase excretion while decreasing vitamin D availability and lowering serum levels. Increased risk of bone loss, osteoporosis, and fractures with long-term oral steroid use.	Supplement vitamin D and calcium. Monitor bone and 25(OH)D status with steroid use > 1 month. Promote sunlight exposure and exercise.
Estrogens/progestins Hormone replacement therapy (HRT) ⊕⊕/✗✗	Synergistic interaction, especially with osteoporosis. Vitamin D assists calcium absorption, and both enable estrogen in inhibiting osteoclastic activity and bone resorption and maintaining bone mineralization. Progestins may counter benefit.	Coadminister vitamin D and calcium (separate intake), possibly bisphosphonates. Monitor bone, 25(OH)D, and HDL. Promote sunlight and exercise.
Heparin, unfractionated ◈≈≈/≈≈	Heparin therapy is associated with bone loss. Heparin may also inhibit formation of $1,25(OH)_2D$ by kidneys. Risks of bone loss and associated nutrient depletion with extended heparin use are significant. Limited evidence supporting protective effect of oral vitamin D.	Coadminister vitamin D and calcium, possibly as hydroxyapatite. Monitor bone and $1,25(OH)_2$ status with heparin use > 1 month.
Isoniazid (INH) ≈≈	Isoniazid can lower levels of both activated vitamin D and calcium levels; can also inhibit hepatic mixed-function oxidase activity, hepatic 25-hydroxylase and renal 1α-hydroxylase and reduce corresponding vitamin D metabolites. Drug-induced vitamin D deficiency can produce hypocalcemia and elevate parathyroid hormone. Nutrient support unlikely to interfere with drug's therapeutic activity.	Supplement vitamin D and calcium when INH used for > 1 month. Promote sunlight exposure. Monitor 25(OH)D and bone status.
Ketoconazole ⊕✗	Ketoconazole inhibits P450 enzymes to block adrenal steroidogenesis; also inhibits both synthesis of activated vitamin D and its metabolism by 1 alpha-hydroxylase and 24-hydroxylase, thus maintaining $1,25(OH)_2$-vitamin D levels if it is supplemented. Ketoconazole reduces calcium (and 1,25-D) in hypercalcemia and sarcoidosis.	Monitor for vitamin D deficiency with long-term use. Calcitriol may be necessary. Half-life of administered calcitriol prolonged in presence of ketoconazole.
Neomycin ≈≈≈/◈	Long-term use of neomycin decreases absorption and/or increases elimination of many nutrients, including vitamin D. Risk of deficiency and sequelae.	Supplement multivitamin-mineral with extended use.

Continued

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Orlistat ≈≈≈	Orlistat binds fat to prevent absorption and can interfere with absorption of vitamin D and other fat-soluble nutrients. Possible risk of significant deficiency.	Supplement multivitamin with extended use. Separate intake timing.
Raloxifene ⊕⊕	Synergistic interaction; vitamin D assists calcium absorption, and both enable raloxifene in inhibiting bone resorption.	Coadminister D_3 plus calcium. Monitor 25(OH)D and bone status. Promote sunlight exposure and exercise.
Rifampin ≈≈/◇≈≈	Rifampin induces cytochrome P450, resulting in decreased plasma levels of 25-hydroxycholecalciferol (25-OHD). Risk of significant deficiency uncertain.	Supplement D_3 when rifampin > 1 month. Monitor 25(OH)D status.
Thiazide diuretics ◇◇/✗✗	Thiazides reduce calcium excretion and could potentially lead to hypercalcemia (rare) and changes in vitamin D metabolism. Significance of interaction uncertain.	Monitor serum calcium.
Thioridazine ✗✗✗	Cholecalciferol inhibits hepatic cytochrome P2D6 and may decrease the metabolism of thioridazine. Concurrent use might increase activity and adverse effects of drug.	Monitor vitamin D status; supplementation may be appropriate but only under close supervision. Consider alternatives to thioridazine.
Verapamil Calcium channel blockers ✗✗✗/◇◇◇/◇◇	Vitamin D can increase calcium availability, which opposes verapamil's activity as calcium antagonist. Excess vitamin D might theoretically contribute to hypercalcemia on rare occasions, which in turn might theoretically precipitate cardiac arrhythmia in patients taking verapamil. Minimal evidence and low probability but potentially severe.	Concurrent supplementation with vitamin D (and calcium) may be appropriate but only under close supervision. Consider bone support needs.

NUTRIENT DESCRIPTION

Chemistry and Forms

Vitamin D is the generic term for compounds that exhibit the biological activity of calciferol: vitamin D_2 (ergocalciferol), vitamin D_3 (cholecalciferol), $1\alpha(OH)D_3$ (alfacalcidol), $25(OH)D_3$ (calcifediol, calcidiol), $1,25(OH)_2D_3$ (calcitriol), and dihydrotachysterol.

Physiology and Function

Vitamin D functions as both a fat-soluble vitamin and a hormone. From dietary sources, vitamin D is absorbed from the small intestine in the presence of bile and is transported into the circulation via the lymph in chylomicrons (similar to vitamin A transport). Vitamin D can also be synthesized in the skin as a result of direct exposure to the ultraviolet light in sunlight (UVB radiation) through the conversion of 7-dehydrocholesterol to cholecalciferol (vitamin D_3). This ability of animals to produce vitamin D from a cholesterol derivative makes the nutrient a "conditionally essential" vitamin. On entering the circulation from either the diet or the skin, vitamin D_3 is bound to the vitamin D–binding protein and transported to the liver. Two successive hydroxylations of vitamin D, first in the liver (to 25-hydroxycholecalciferol) and then in the kidneys, produce the hormonally active form, calcitriol, or 1,25-dihydroxycholecalciferol (1,25-dihydroxyvitamin D_3), in coordination with the parathyroid glands and calcium-sensitive parathyroid hormone (PTH, parathormone) secretion.

Calcitriol binds to the *vitamin D receptor* (VDR), a nuclear transcription factor that regulates gene expression. When the calcitriol/VDR complex subsequently combines with the *retinoic acid X receptor* (RXR), the resulting VDR/RXR heterodimer can interact with the vitamin D–responsive elements (VDREs) within the DNA. This interaction between the VDR/RXR heterodimer and a VDRE alters the rate of transcription of a related gene and thereby regulates the activity of vitamin D–dependent calcium transporters in the small intestine, osteoblasts in bone, and the 1-hydroxylase enzyme in the kidneys. Defects in the vitamin D receptor lead to hypocalcemic vitamin D–resistant rickets, congenital total lipodystrophy, and persistent müllerian duct syndrome. Research suggests that bone may be more responsive to exercise in some genotypes of VDR than in others,[1] and that gene-environment interactions such as leisure physical activity and VDR genotype may play a role in maintaining the bone mineral density (BMD) at the lumbar spine in active postmenopausal women, especially in older active women.[2]

The vitamin D endocrine system is responsible for maintaining tight regulation of serum calcium levels within the narrow range critical to bone metabolism and healthy functioning of the nervous system. Calcitriol mediates the intestinal absorption and blood levels of calcium and phosphorus. It facilitates mineral deposition into bone, modulates bone mineralization and demineralization, and enhances muscle strength and balance. Vitamin D is necessary to calcium absorption and increases the absorption of calcium from the intestine (by stimulating the synthesis of calcium-binding protein and the epithelial calcium channel) and maintains serum calcium levels in the normal range; thus increasing resorption of calcium from bone as well as facilitating calcium storage in the bones. Consequently, even though it initially causes bone resorption, the net effect is to increase calcium deposition in the bone. In addition to promoting calcium absorption, calcitriol mediates the intestinal absorption of phosphorus, possibly magnesium and zinc as well, and may promote renal tubule phosphate resorption. Vitamin D is stored in body fat.

Vitamin D also plays many important roles in hormonal regulation and immune function. It helps maintain adequate blood levels of insulin and may assist the metabolism of sugar. Vitamin D may also assist healthy thyroid function, and the active form of vitamin D_3 may have a mechanism of action similar to thyroid hormone. Vitamin D and VDRs participate in the regulation of cell growth and development, particularly white blood cells and epithelial cells. In particular, the presence of VDRs in T lymphocytes suggests that vitamin D facilitates the development, activity, and response of T cells against antigens (and in autoimmune disorders).

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Vitamin D is used to prevent osteoporosis and osteoporotic fractures, and intake is associated with reduced risk of breast cancer, colorectal cancer, prostate cancer, as well as cancers of

the lung, skin (melanoma), colon, and bone. Administration of vitamin D in conjunction with bisphosphonate therapy (e.g., alendronate, risedronate, or etidronate) or exogenous hormone therapy (e.g., HRT) may enhance clinical outcomes in preventing and treating osteoporosis. A range of autoimmune diseases, particularly type 1 diabetes mellitus, rheumatoid arthritis, and multiple sclerosis, may be responsive to integrative therapeutics employing vitamin D, especially when they involve a VDR gene polymorphism. Calcitriol, the active metabolite of vitamin D, has been found to inhibit the growth of human prostate cancer cells in vitro; however, findings from preliminary human trials have been disappointing for its use (or that of analogs) as part of innovative protocols in the treatment of hormone-refractory prostate cancer.

Historical/Ethnomedicine Precedent

The physiological parameters of vitamin D may be premised on the ancient origins of humans in equatorial Africa. The high level of exposure to sun inherent to such an interaction with the environment may play a fundamental role in the high susceptibility for insufficiency or deficiency among modern humans less exposed to the sun, especially for dark-skinned individuals, because melanin acts as an ultraviolet absorber.

Possible Uses

Atherosclerosis, autoimmune diseases, breast cancer, burns, cancer prevention, celiac disease, digestive system cancers (oral, esophageal, stomach, pancreas, colorectal; risk reduction, especially in individuals with dark skin), Crohn's disease, depression (particularly seasonal affective disorder), diabetes mellitus, epilepsy, falls (prevention, especially in the elderly), fractures (especially in the elderly), hearing loss, hyperparathyroidism (secondary), hypertension, hypoparathyroidism, migraine headaches, multiple sclerosis, obesity, osteoarthritis, osteomalacia, osteoporosis, prevention of vitamin D deficiency, prostate cancer, psoriasis, rheumatoid arthritis (risk reduction), rickets, scleroderma, skin cancer (risk reduction), tuberculosis.

Deficiency Symptoms

Rickets, osteomalacia, osteoporosis, and fracture risk remain the most obvious and well-known outcomes associated with vitamin D deficiency. Researchers have increasingly expressed concern that the low levels of vitamin D found in a large percentage of Americans and Europeans may be associated with increased risk of a range of conditions, including cancer, heart disease, hypertension, diabetes, multiple sclerosis, and diminished immune status. The classic groups known for increased risk of deficiency are breast-fed infants, individuals on vegetarian diets, the elderly, individuals with fat malabsorption or chronic kidney disease, and individuals with compromised sun exposure due to lifestyle, climate, season, or cultural practices. Other significant etiologies include alcoholism, burns (and burn scarring), Crohn's disease, Cushing's disease, dark skin, decreased consumption of vitamin D, hypothyroidism, anticonvulsant drug therapy, kidney or liver disease, malabsorption (as in celiac disease or after intestinal surgery), ulcerative colitis, and vitamin D–resistant rickets. Vitamin D receptor polymorphic alleles have been linked to diabetes mellitus and colon cancer.[3,4] Low dietary calcium intake may enhance the phenotypic expression of VDR gene polymorphisms.[5]

Awareness of previously unrecognized vitamin D deficiency and its implications in long-term pathological processes has been growing in recent years.[6,7] Chapuy et al.[8] (1997) reported that one of seven adults may be deficient in vitamin D. Similarly, a study in 1998 by Thomas et al.[9] found that 37% of the total group surveyed were deficient in vitamin D, even though their reported diets should have provided the currently recommended levels of vitamin. This study also found that 42% of hospitalized patients under age 65 were deficient in vitamin D. Overall, vitamin D inadequacy has been reported in up to 57% of general medicine inpatients in the United States.[10] Spanish researchers found that healthy postmenopausal women in modern societies have an extremely high prevalence of vitamin D deficiency.[11] Likewise, young adults exhibit an unexpectedly high incidence of vitamin D insufficiency.[12] Vitamin D deficiencies may also raise the risk of prostate cancer by disrupting the relationship between androgens and VDR in prostate cells.[13]

Dietary Sources

Cod liver oil, oily cold-water fish (salmon, mackerel, herring), butter, egg yolks, vitamin D–fortified milk, and orange juice.

Most vitamin D in humans is derived from endogenous synthesis subsequent to sun exposure rather than from dietary sources. Vitamin D is found primarily in foods of animal origin, unless they are fortified. Cod liver oil is considered an excellent dietary source. Vegetables are usually low in vitamin D, although mushrooms, if irradiated, can be a significant source of vitamin D. Milk used to make cheese or yogurt is usually not fortified with vitamin D. Human milk contains the 25-hydroxycholecalciferol form of D, possibly to compensate for the limited ability of the liver in infants to achieve the first hydroxylation of cholecalciferol. The vitamin D content in human milk varies with maternal sun exposure and vitamin D intake.

Sunshine

With exposure to ultraviolet light, the skin synthesizes vitamin D. It is estimated that 20 minutes, with face and arms exposed, will stimulate about 600 to 1000 IU per day, during spring, summer, and fall in temperate regions, and year-round in tropical and subtropical regions. Enough sun or UVB exposure to produce minimal skin erythema (known as the *minimal erythemic dose*) can produce 10,000 to 20,000 IU in about an hour. Adequate amounts of vitamin D can theoretically be synthesized and stored in fat to carry an individual through the winter. In temperate latitudes, above 35° to 50°, a minimum of 15 minutes of sun exposure on the arms, face, and hands three times per week in the morning or late afternoon during the spring, summer, and fall is needed to avoid vitamin D deficiency at the end of winter. However, research indicates that, in actuality, many individuals in higher latitudes, especially with seasonal clothing, overcast climates, and minimal time outdoors, do not receive adequate sun exposure to avoid compromised vitamin D status. Sun exposure with sunscreen significantly prevents skin synthesis of vitamin D.

Dosage Forms Available

Capsules, injection (IM), liquid, tablets. Intramuscular (IM) form is not available in the United States.

Oral dosing (with meals) is preferred, but malabsorption associated with gastrointestinal, liver, or biliary disease may necessitate IM injection.

Nutrient Preparations Available

Cholecalciferol (vitamin D_3) is more potent and bioavailable than ergocalciferol (D_2).

Dosage Range

Adult

Dietary: The adequate intake of vitamin D (cholecalciferol, or vitamin D_3) is 5 µg (200 IU) per day for adults age 19 to 50 years, 10 µg (400 IU) for adults age 51 to 70 years, and 15 µg (600 IU) for adults 71 years and older.

Supplemental/Maintenance: 10 µg (400 IU) per day. However, in some cases this may be unnecessary, given consistent adequate direct exposure to the sun, usually 20 minutes per day. Supplement with cod liver oil if 25(OH)D levels are low (1 tsp per 50 pounds of body weight). One tablespoon of cod liver oil provides approximately 1200 IU (30 µg) of vitamin D_3.

A dose of 20 µg (800 IU) per day for individuals, especially the elderly, not adequately exposed to sunlight or living in farther northern or southern latitudes.

Pharmacological/Therapeutic: 800 to 2000 IU per day, including dietary sources, under supervision of a physician or health care professional experienced in nutritional therapeutics.[14,15] Dosages used in clinical studies range from 5 µg (200 IU) to 250 µg (10,000 IU) daily. Significantly higher doses are often used in the treatment of secondary hypoparathyroidism, vitamin D–resistant rickets, nutritional rickets and osteomalacia, and familial hypophosphatemia.

Toxic: The current official tolerable upper intake level (UL) is 50 µg (2000 IU) per day. However, many experts in the field strongly support raising the UL to at least 4000 IU, and 10,000 IU may be tolerable for most individuals, but such a daily dose should be medically monitored.

Adverse effects have been reported at concentrations ranging from 250 to 1250 µg (10,000-50,000 IU) per day.

Pediatric (<18 years)

Dietary: The adequate intake (AI) of vitamin D (cholecalciferol, or vitamin D_3) is 5 µg (200 IU) per day for infants and children up to 18 years.

Supplemental/Maintenance: One teaspoon of cod liver oil per 50 lb/wt. Sun exposure of 20 minutes daily is adequate and preferable. Do not give cod liver oil when sun exposure is being implemented.

Pharmacological/Therapeutic

Premature infants: 10 to 20 µg (400-800 units) per day, up to 750 µg (30,000 IU) per day.
Infants and healthy children: 10 µg (400 IU) per day.

Significantly higher doses are often used in the treatment of hypoparathyroidism, nutritional rickets and osteomalacia, vitamin D–resistant rickets, and familial hypophosphatemia. Vitamin D receptor defects, specifically tissue resistance to vitamin D_3 or vitamin D–dependent rickets (VDDR), are usually treated with 20 µg/day of the bioactive form, calcitriol, or 5 mg/day of the dietary form, vitamin D_2, plus oral calcium and phosphate.[16]

Toxic: UL for infants (0-12 months) is 25 µg (1000 IU) per day and for children (1-18 years) is 50 µg (2000 IU) per day.

Note: Requirements depend on the exposure of a person's skin to ultraviolet radiation. The intensity of exposure is also a factor. The latitude determines how much exposure to sunlight the person requires to synthesize adequate levels of vitamin D. Pollution, clouds, and skin color also affect an individual's ability to produce vitamin D. The darker the skin, the less vitamin D will be produced (up to 95% blocked). However, with longer exposure times, even with the darkest skin color, sufficient levels of vitamin D are produced. Glass and topical sunscreens block UV light.

Laboratory Values

Laboratory assessment of vitamin D status has been in a state of controversy and evolution in recent years, particularly since the effects of mild vitamin D deficiency or insufficiency have become more widely recognized.

Plasma 25(OH)-Vitamin D

This assay reflects body reserves. Plasma levels less than 25 nmol/L indicate deficiency.

However, results from laboratories doing 25-hydroxyvitamin D (25-OHD) tests vary widely.[17] Reference ranges from most labs are too low. Optimal serum levels of 25-OHD to avoid increases in PTH are at least 20 ng/mL,[18] but may actually be in the range of 45 to 55 ng/mL (115-140 nmol/L). Heaney et al.[19,20] suggest that the appropriate serum 25-OHD level is 32 ng/mL.[8] Concurrent parathyroid tests (PTH) may elucidate equivocal laboratory findings because one could expect a high PTH if there is a low vitamin D concentration in the blood.

Plasma 1,25(OH)$_2$-Vitamin D

This assay measures the active form of the vitamin. As 25-OHD levels drop, PTH secretion increases (secondary hyperparathyroidism), which maintains the 1,25$(OH)_2$-vitamin D level in the normal range. For this reason, measuring the 25-OHD level is necessary to diagnose vitamin D deficiency or insufficiency. Normal 1,25$(OH)_2$D levels are 48 to 100 pmol/L.

Also, measure serum calcium, blood urea nitrogen (BUN), and phosphorus every 1 to 2 weeks; and monitor bone density regularly until stabilized.

Serum calcium concentration times phosphorus concentration should not exceed 70 mg/dL to avoid ectopic calcification; ergocalciferol levels: 10 to 60 ng/mL; serum calcium: 9 to 10 mg/dL; phosphorus: 2.5 to 5.0 mg/dL.

SAFETY PROFILE

Overview

Vitamin D is generally well tolerated, and excessive doses from sunlight exposure or dietary source are considered highly improbable, if not impossible. Its UL of 50 µg (2000 IU) per day reflects that vitamin D has long been considered the most likely of all vitamin supplements to cause toxicity. Although a revised consensus has developed in recent years among researchers and some clinicians, regulatory and institutional guidelines are only gradually beginning to respond to and integrate the new data into their recommendations.

Adverse effects have been reported at concentrations ranging from 250 to 1250 µg/daily.[21] Hypervitaminosis D has generally been associated with intake of 625 to 1500 µg (25,000-60,000 IU) daily for 1 to 4 months, or several years of vitamin D supplementation at 250 to 1250 µg (10,000-50,000 IU) daily, and has never been associated with sun exposure. Published case reports of vitamin D toxicity with hypercalcemia, for which the 25(OH)D concentration

and vitamin D dose are known, all involve intake of at least 1000 µg (40,000 IU) per day, and only one case occurred at a level of intake under 40,000 IU/day.[14]

However, emerging evidence and the opinions of many vitamin D researchers now suggest that the daily value (DV) of 400 IU for vitamin D, which was based on the amount necessary to prevent rickets in infants (initially given as 5 mL of cod liver oil 100 years ago) is an order of magnitude below the amount necessary for older adults, and those not exposed to sun without sunscreen on a regular basis, to achieve and maintain blood levels of vitamin D that are optimum for bone health and cancer prevention.[16,22-33] "Estimates of the population distribution of serum 25(OH)D values, coupled with available dose-response data, indicate that it would require input of an additional 2600 IU/d (65 mcg/d) of oral vitamin D_3 to ensure that 97.5% of older women have 25(OH)D values at or above desirable levels."[34] Absent lymphoma or granulomatous disease, which can cause vitamin D sensitivity, it appears that long-term ingestion of greater than 10,000 IU/day is necessary to cause vitamin D toxicity and hypercalcemia.

Nutrient Adverse Effects

General Adverse Effects

Excessive levels of vitamin D intake over an extended period can lead to headaches, kidney stones, and weight loss. Less common symptoms include diarrhea, increased thirst, increased urination, irritability, and failure to gain weight in children. More extreme consequences include blindness, deafness, and potentially death. Elevated vitamin D levels (as well as vitamin D deficiency) may be related to increased risk of prostate cancer.[35] Vitamin D intake increases both calcium and phosphorus absorption. Although the increased levels of calcium associated with enhanced vitamin D status may be an indicator of benefit for those at risk for bone loss, elevated blood levels of calcium may also be associated with increased risk of heart disease. Elevated serum calcium levels induced by hypervitaminosis D are responsible for many of its primary adverse effects.

Acute overdose is associated with increased urinary frequency, nausea, vomiting, loss of appetite, diarrhea, muscle weakness, dizziness, and calcification of heart, blood vessels, and lungs; symptoms reverse after overdosing is discontinued.

Adverse Effects Among Specific Populations

Individuals with sarcoidosis, other granulomatous diseases, and certain types of lymphoma may quickly develop elevated levels of 1,25(OH)$_2$-vitamin D_3 (the activated form), if supplemented with cholecalciferol or other vitamin D precursor, because of autonomous conversion of 25-OHD to the active hormone, 1,25(OH)$_2$D. Elevated levels of activated vitamin D significantly increase risk of hypercalcemia, which might require treatment with hydration, intravenous bisphosphonates, ketoconazole, hydroxychloroquine (Plaquenil), and corticosteroids, as well as avoidance of dietary sources of vitamins D_2 and D_3 and calcium.

Pregnancy and Nursing

Vitamin D enters breast milk and is considered compatible at usual dosage levels.

Infants and Children

Vitamin D intakes of 50 to 75 µg (2000-3000 IU) per day may cause toxicity symptoms in some children. Also, some hypersensitive infants have developed toxicity symptoms at 1000 IU/day.

Most cases of toxicity involve the intake of 625 to 1500 µg (25,000-60,000 IU) per day for 1 to 4 months.

Children taking 250 µg (10,000 IU) per day for 4 months can develop the following toxicity symptoms, related to hypercalcemia: headaches, weakness, nausea and vomiting, constipation, polyuria, polydipsia, diarrhea, and calcification of soft tissues, such as kidneys, lungs, tympanic membrane, or ears.

Contraindications

Hypercalcemia, hyperparathyroidism (primary), hypersensitivity to cholecalciferol or any component of the formulation, malabsorption syndrome, sarcoidosis, granulomatous disease, lymphoma; evidence of vitamin D toxicity. If vitamin D insufficiency or deficiency is documented in a patient with lymphoma, cautious supplementation of vitamin D_3 with monitoring of blood levels of both forms of vitamin D and calcium may be undertaken. Not all lymphomas will autonomously convert 25-OHD to its activated form, and no predictive tests yet exist for this capability. Successful treatment of the lymphoma with a complete response obviates the risk of vitamin D hyperconversion. Vitamin D sufficiency may decrease risk of relapse in treated lymphoma patients because vitamin D deficiency is associated with increased risk of developing the disease (along with several other cancers, including breast, colon, and prostate).

Precautions and Warnings

Administer with extreme caution in patients with impaired renal function, heart disease, renal stones, or arteriosclerosis.
Administer concomitant calcium supplementation.
Maintain adequate fluid intake.
Avoid hypercalcemia, although not likely in absence of 1,25(OH)$_2$-vitamin D_3 excess.

Caution may be appropriate with renal function impairment with secondary hyperparathyroidism. However, impaired renal function is often associated with a need to administer prescription vitamin D as well as D_3 because second hydroxylation of the 25-OH form is lacking. Furthermore, secondary hyperparathyroidism is an indication for D_3 therapy.

INTERACTIONS REVIEW

Strategic Considerations

Several classes of common pharmacological agents interact with vitamin D and its metabolic processes. These interactions take on greater significance in light of the elevated probability of vitamin D deficiency in many of the patient populations likely to be prescribed the medications under consideration. More broadly, the occurrence of vitamin D deficiency has been recognized as being more widespread than previously believed, and in turn the implications of vitamin D insufficiency for health maintenance and disease prevention have become better understood. Thus, although conventional medical practice and governmental nutritional policies have focused on prevention of short-latency deficiency diseases, vitamin D represents a prime example of the growing awareness of the central role of nutritional factors in health maintenance and prevention of long-latency deficiency diseases. Factors such as lack of time outdoors with significant sunlight exposure, air pollution, cultural practices,

and geographic population distribution all add to the subtle but profound significance of seasonal decrease in sunlight availability, even in areas generally considered as "sunny."[7,9,11,36,37] The combined effect of these many factors contributes to what some experts have described as an "epidemic" of vitamin D deficiency, affecting 20% to 60% of the population.

The issues of pervasive vitamin D deficiency status and underutilization of laboratory assessment for 25-hydroxyvitamin D levels influence and limit research design, interpretation, and clinical practice within conventional medicine. For example, in 2005, two randomized controlled trials of calcium carbonate and cholecalciferol (vitamin D_3) administration for prevention of fractures in primary care reported widely publicized conclusions that such nutrient supplementation provided no value in preventing fractures.[38,39] Such declarations were made despite disclosures that (1) vitamin D levels had been tested in only a small sample of the subjects in one of the studies; (2) vitamin D deficiency appeared to be common within the subject populations, as indicated by responses to vitamin D supplementation; (3) quality control of the supplements was very poor, and compliance was marginal and declined over time (e.g., 63%, or as low as 45%); and (4) the use of calcium carbonate in a population of older and often hypochlorhydric subjects would be considered suboptimal by many, if not most, experienced practitioners of nutritional therapeutics. Digestion of calcium carbonate relies on the integrity of gastric function and the bowel culture to produce the ionizing acids. Thus, gastrointestinal adverse effects, typical of calcium carbonate, were cited as a major factor in greater noncompliance with calcium intake.

In the study in which 1% of the subjects had their vitamin D levels actually measured, there was only a marginal increase after 1 year of supplementation with 800 IU of vitamin D per day (although some supplements, when analyzed, contained as little as 372 IU, mean value, per tablet). Average 25-OHD levels at beginning of the study (15 ng/mL) were in the range of severe deficiency and after 1 year improved only to 24 ng/mL, still well below what many vitamin D researchers consider to be adequate levels (30-40 ng/mL).[40]

Subsequently, in a trial involving 944 healthy Icelandic adults, Steingrimsdottir et al.[41] found that with 25-OHD levels below 10 ng/mL, maintaining calcium intake above 800 mg/day appeared to normalize calcium metabolism, as determined by the PTH level, but in individuals with higher 25-OHD levels, no benefit was observed from calcium intake above 800 mg/day. Likewise, Jackson et al.[42] found that the combination of 1000 mg elemental calcium (as calcium carbonate) and 400 IU vitamin D daily did not appreciably reduce risk of hip fracture over 7 years, except in those who took their nutrients regularly. Thus, among adherent women (i.e., those who followed the treatment protocol 80% of the time), the supplements reduced hip fractures by 29%. Nevertheless, the relatively low dose of vitamin D, the use of calcium carbonate (a less-than-optimal form in the opinion of many and one associated with reduced compliance), and the late start and relatively limited duration of supplementation suggest that the treatment protocol was less than adequate (unless consistently adhered to) and thus render these findings less than conclusive. Such studies also indicate the importance of nutrient support throughout adulthood, as opposed to beginning it past midlife. Clearly, further research on calcium and other minerals involved in bone metabolism needs to take into account, and preferably optimize, vitamin D status.

Notably, the main conventional pharmacological intervention against osteoporosis is *antiresorptive drugs*, such as bisphosphonates, for which almost every clinical trial has included coadministration of calcium or vitamin D. Moreover, the decontextualization and narrow focus of these studies highlight the shortcomings of standard research methodology and clinical practice to account for the broad factors of aging, lifestyle, activity level, drug depletions, and poor nutritional status characteristic of the populations in question, as well as the complex nature of bone health and its reliance on interdependencies of multiple nutrients and tissues, rather than such a narrow focus on supplemental calcium and vitamin D. As public and practitioner attention on vitamin D grows, it may prove a pivotal issue in expanding perceptions and awareness, analysis, and intervention through a broad integrative model more accurately reflecting patient needs and scientifically comprehending the breadth and complexity of the processes involved.[14,24,28,37]

The well-known interactions between vitamin D and pharmaceutical medications cluster into several main groups. The use of calcium and vitamin D appears to enhance the bone-maintaining effectiveness of hormone replacement therapy (HRT) and bisphosphonates, especially for women who already have osteoporosis; this benefit appears greater for women supplementing with calcium citrate than for those using calcium carbonate. Anticonvulsants, particularly phenobarbital and phenytoin, may reduce serum levels of calcidiol (25-hydroxycholecalciferol, calcifediol) by altering hepatic metabolism of vitamin D. Notably, physicians prescribing agents that impair vitamin D function for extended periods (e.g., anticonvulsants, opioids, oral cortiocosteroids) usually do not advise or prescribe adequate countermeasures, whether vitamin D and calcium, bisphosphonates, or the combination, to effectively address the common occurrence of drug-induced decreases in bone mineral density and increased risk of fracture.[43,44] Numerous medications that alter fat absorption, such as cholestyramine, colestipol, mineral oil, orlistat, and olestra, can interfere with intestinal absorption of vitamin D. Ketoconazole can reduce serum levels of calcitriol. Conversely, excessive vitamin D intake may, in rare cases, induce hypercalcemia and could theoretically precipitate cardiac arrhythmia in patients receiving cardiovascular medications such as verapamil or digoxin. Moreover, cardiac glycosides could potentially increase toxicity. Thiazide diuretics may increase vitamin D effects. Finally, it is now recognized that cholecalciferol inhibits CYP2C8/9, 2C19, and 2D6, although the full implications of such activity and the potential effects on pharmaceuticals metabolized by these enzymes have yet to be fully investigated and documented.

Because vitamin D toxicity from supplemental sources is a real (though improbable) possibility, health care providers are reminded to counsel their patients to avoid taking more than the recommended amount of vitamin D, and to take it in conjunction with a calcium supplement and possibly a special diet. The encouragement of greater exposure to sunlight (outdoors) cannot be overemphasized. Although contrary to prevailing dogma of the past decade and as yet poorly studied, it is becoming increasingly evident that use of high-potency sunscreens that block UVB may significantly contribute to vitamin D deficit. Oral supplementation can be used to compensate for lack of adequate UV exposure from sunlight. However, significantly higher amounts of supplementation may be necessary than previously believed and currently available in most vitamin preparations. Titrating intake to blood level of 25-OHD is the most reliable way to ensure adequate intake.

Although some innovative therapeutic strategies are emerging using vitamin D analogs, most examples of such approaches are considered separately in a brief review later.

NUTRIENT-DRUG INTERACTIONS

Allopurinol

Allopurinol (Loporin, Zyloprim)

Interaction Type and Significance
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
2. Probable

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action
The uric acid–lowering agent allopurinol may elevate serum concentrations of 1,25-dihydroxycholecalciferol, the active form of vitamin D. Uric acid may directly decrease the serum concentration of $1,25(OH)_2$-vitamin D_3 in patients with gout by inhibiting 1-hydroxylase activity.

Research
Takahashi et al.[45] measured the serum concentrations of $1,25(OH)_2$-vitamin D_3, 25(OH)-vitamin D_3, and parathyroid hormone (PTH) in 82 male patients with primary gout whose serum uric acid was significantly higher than that of 41 normal control male subjects. The patients with gout exhibited a significantly decreased serum concentration of $1,25(OH)_2$-vitamin D_3, which was corrected as uric acid levels dropped. These researchers reported that administration of allopurinol for 1 year caused a significant increase in their serum $1,25(OH)_2$-vitamin D_3 concentration (along with a significant decrease in their serum uric acid concentration). Notably, the serum concentrations of 25(OH)-vitamin D_3 and PTH were not affected.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Individuals diagnosed with gout may have compromised vitamin D status and should be assessed for vitamin D deficiency. Coadministration of a uric acid–lowering agent such as allopurinol may elevate $1,25(OH)_2$-vitamin D_3 levels. Supplementation with vitamin D (5-10 μg/day) may be advisable and is unlikely to present any significant risk, particularly under reasonable supervision and regular monitoring.

Androgen-Deprivation Therapy

Antiandrogens: Bicalutamide (Casodex), cyproterone (Androcur, Cyprostat, Cyproteron, Cyprone, Cyprohexal, Ciproterona, Cyproteronum, Neoproxil, Procur, Siterone), flutamide (Chimax, Drogenil, Eulflex, Eulexin), nilutamide (Anandron, Nilandron).
Gonadotropin-releasing hormone (GnRH) agonists/analogs: Goserelin (Zoladex), leuprolide (Eligard, Lupron, Lupron Depot, Viadur), triptorelin (De-capeptyl Trelstar, Trelstar LA).

Interaction Type and Significance
○ **Prevention and Reduction of Drug Adverse Effect**
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
2. Probable

Evidence Base:
● **Consensus**

Effect and Mechanism of Action
Decreased levels of sex hormones are generally associated with increased risk of diminished bone mineral density (BMD) and osteoporosis. Supplementation of vitamin D can optimize and preserve bone mass, which tends to be adversely affected by androgen-deprivation therapy (ADT) and is associated with increased risk of osteoporosis and fractures.

Research
Research directly investigating prevention and treatment of osteoporosis caused by ADT is limited. Normally, the incidence of osteoporotic fractures usually increases a decade later in men than in women. Osteoporosis in men with gonadal steroid deficiency can derive from a variety of causes. Gonadotropin-releasing hormone agonists (which, after causing an initial surge in testosterone, result in castrate levels that are maintained as long as the drug is administered) hasten this process and increase bone loss, increasing the risk of osteoporosis and fractures, which have been widely documented in men prescribed ADT for the treatment of prostate carcinoma.[46-53] Four retrospective studies have shown a significant association between ADT and elevated fracture risk in men with prostate cancer.[48,54-56] In particular, with GnRH agonists, men with fractures had lower BMD and higher biochemical markers of bone resorption than men without fractures.[55] Collectively, the available studies indicate that the first year of ADT results in a 5% to 10% decrease in BMD in men with prostate cancer, an effect greater than that associated with menopause.[57] Furthermore, in a cross-sectional study of hormone-naive men with prostate cancer, Smith et al.[58] observed vitamin D deficiency and inadequate dietary intake of calcium in 17% and 59%, respectively.

Smith et al.[59] also found that concurrent treatment with calcium, vitamin D, and pamidronate (a bisphosphonate drug) during ADT increases serum concentrations of both 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D. Bisphosphonates have come to play an important role in supporting bone mass.[59-62] Coadministration of vitamin D (and calcium), particularly with bisphosphonates, is generally accepted.[51] The rationale and supporting research are further discussed in the Bisphosphonates section.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
As with postmenopausal women and HRT, concomitant calcium and vitamin D enable and enhance the fundamental preventive support provided by diet and regular weight-bearing exercise in maintaining (or restoring) bone health, particularly bone mass and BMD. Smoking cessation, moderate alcohol consumption, and other supportive lifestyle modification should be also encouraged. The administration of bisphosphonates constitutes a further intervention as part of conventional care. Clinical management should evolve in response to the results of urinary assessment of bone breakdown (e.g., deoxypyridinium metabolites) and radiographic, DXA (dual-energy x-ray absorptiometry), ultrasound, or other techniques for BMD assessment. Oral intake of the bisphosphonate and calcium should be separated by at least 2 hours.

Anticonvulsant Medications, Including Phenobarbital, Phenytoin, and Valproic Acid

Evidence: Divalproex semisodium, divalproex sodium (Depakote), gabapentin (Neurontin), phenobarbital (phenobarbitone; Luminal, Solfoton), phenytoin (diphenylhydantoin; Dilantin, Phenytek), sodium valproate (Depacon), valproate semisodium, valproic acid (Depakene, Depakene Syrup).
Extrapolated, based on similar properties: Carbamazepine (Carbatrol, Tegretol), clonazepam (Klonopin), clorazepate (Tranxene), diazepam (Valium), ethosuximide (Zarontin),

ethotoin (Peganone), felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), lamotrigine (Lamictal), levetiracetam (Keppra), mephenytoin, mephobarbital (Mebaral), methsuximide (Celontin), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), piracetam (Nootropyl), primidone (Mysoline), topiramate (Topamax), trimethadione (Tridione), vigabatrin (Sabril), zonisamide (Zonegran).

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Phenobarbital and related anticonvulsants are inducers of cytochrome P450 and the mixed-function oxidase system. Phenobarbital impairs bioavailability of vitamin D. Phenytoin and phenobarbital may reduce serum levels of 25(OH)D (calcidiol) by altering hepatic metabolism of vitamin D, at least in part by accelerating its metabolism.[63, 64] Antiepileptic drugs (AEDs) that induce the enzyme CYP3A4 are of particular concern because 3A4 degrades vitamin D, which can create effects consistent with secondary hyperparathyroidism; AEDs that induce 3A4 include phenytoin, phenobarbital, carbamazepine, oxcarbazepine, and felbamate. Vitamin D therapy does not appear to alter serum phenytoin levels, but phenytoin may limit the ability of some individuals to respond to vitamin D therapy or may require larger doses of vitamin D to maintain optimal blood levels of 25-OHD. Thus, anticonvulsants impair mineralization, leading to increased risk of osteomalacia and osteoporosis.

High-dose vitamin D therapy can significantly counter vitamin D depletion and improve BMD and prevent bone loss associated with anticonvulsant treatment.

Research

Long-term therapy with phenytoin and other anticonvulsants can disturb vitamin D and calcium metabolism and result in osteomalacia. Both epilepsy and anticonvulsant medications are independent risk factors for low BMD, regardless of vitamin D levels. Long-term anticonvulsant treatment can cause excessive metabolism and deficiency of vitamin D and is believed to be associated with decreased BMD and bone loss.

In a 1982 study of 30 adult epileptic patients, Zerwekh et al.[65] reported decreased serum 24,25-dihydroxyvitamin D concentration during long-term anticonvulsant therapy (with phenytoin, phenobarbital, or carbamazepine), with phenobarbital-treated patients exhibiting a significant decrease in serum 25(OH)D. They noted that various anticonvulsant agents appear to exert different effects on vitamin D metabolism.

After finding no pattern of low serum levels of vitamin D (25[OH]D) or radiological evidence of osteomalacia or rickets in more than 400 individuals using anticonvulsants in Florida, Williams et al.[66] concluded that the climate provided adequate exposure to sunshine and thereby prevented the development of anticonvulsant-induced osteomalacia or rickets. "In contrast to reports from northern climates, we found minimal evidence of anticonvulsant-induced bone disease." Subsequently, in a controlled trial, Riancho et al.[67] studied 17 ambulatory epileptic children taking anticonvulsants for two seasons with high and low levels of solar radiation and observed that although serum 25-OHD concentrations were normal among medicated subjects during the summer, their levels were significantly lower than those of controls during the winter months.

In initiating a prospective 3-year study, Hunt et al.[68] found that, of 144 children and young adults who required anticonvulsant therapy, 52 were found to have serum alkaline phosphatase (ALP) levels elevated more than two standard deviations (SDs) above normal, and half of these showed signs of rickets or osteomalacia. After slow and gradual but varying rates of response to calcitriol, all patients showed significant lowering of serum ALP levels by 30 months of follow-up. In a later controlled study, Jekovec-Vrhovsek et al.[69] determined that bone strength improved (specifically, BMD increased) in 13 institutionalized children under long-term anticonvulsant therapy who were supplemented for 9 months with 0.25 μg daily 1,25-dihydroxycholecalciferol vitamin D, the activated form of vitamin D, and 500 mg daily calcium.[69]

Telci et al.[70] compared bone turnover in 52 epileptic patients receiving chronic anticonvulsant therapy with 39 healthy volunteers as matched controls and found that the resorption phase of bone turnover is affected during chronic anticonvulsant therapy. Total serum ALP levels (a marker of bone formation) were significantly increased in patients from both genders compared with those of controls. Among male epileptic patients, urinary deoxypyridinoline levels (a marker of bone resorption) were significantly increased and 25-OHD levels significantly reduced compared with controls.[70]

Farhat et al.[71] compared the effects of various AEDs on bone density in 71 adults and children over at least 6 months. More than half the adults and children/adolescents had low serum 25-OHD levels. Although this finding did not correlate with their BMD, AEDs were strongly associated with decreased BMD in the adults, particularly at skeletal sites enriched in cortical bone. Furthermore, lower BMD was more consistently associated with enzyme-inducing agents (e.g., phenytoin, phenobarbital, carbamazepine, primidone) than with medications that did not induce enzymes (e.g., valproic acid, lamotrigine, clonazepam, gabapentin, topamirate, ethosuximide). These researchers concluded: "Generalised seizures, duration of epilepsy, and polypharmacy were significant determinants of bone mineral density."[71]

Although it has been generally established that certain AEDs constituted a risk factor for osteoporosis and fractures in postmenopausal women, data regarding men have largely been lacking. In findings presented at the First North American Regional Epilepsy Congress, Jetter et al.[72] found that "enzyme-inducing AEDs do significantly affect vitamin D, calcium, and parathyroid hormone levels." In this study, researchers focused on phenytoin, phenobarbital, carbamazepine, oxcarbazepine, and felbamate as enzyme 3A4–inducing AEDs. Because 3A4 degrades vitamin D, they set out to determine whether levels of 25-hydroxyvitamin D_3 (25-OH-D_3), PTH, or calcium differed between men taking 3A4 enzyme–inducing AEDs and those taking other types of AEDs. The researchers obtained 25-OH-D_3, intact PTH, and calcium levels in 210 male veterans, age 20 to 89 (average, 58), who had been treated with AEDs for an average of 20.3 years. On analysis, they found that the 126 patients treated with at least one enzyme-inducing AED for at least the past 6 months exhibited an average 25-OH-D_3 level of 19.2 ng/mL, compared with 23.8 ng/mL in those taking non–enzyme-inducing AEDs ($p = .005$). The patients taking enzyme-inducing AEDs had a blood calcium level of 8.83 mg/dL, whereas the 64 treated with only non–enzyme-inducing AEDs for that

period exhibited levels of 9.16 mg/dL ($p = .00009$). The intact PTH levels averaged 52.5 pg/mL for patients on enzyme-inducing AEDs and 38.2 pg/mL for patients on non-enzyme-inducing AEDs ($p = .0002$). The 20 patients treated with divalproex sodium were analyzed separately. The authors concluded that the "findings suggest that a secondary hyperparathyroidism is associated with the use of these drugs and that dietary supplementation of vitamin D may be necessary to prevent osteoporosis." Furthermore, the investigators emphasized that neurologists need to monitor BMD in men treated with these medications, parallel to recommendations regarding female patients.[72]

In 2001, Valmadrid et al.[73] published a survey of practice patterns of neurologists. They found that only 41% of pediatric and 28% of adult neurologists performed routine evaluation of patients taking AEDs for either bone or mineral disease. Further, among those physicians who detected bone disease through such diagnostic testing, 40% of pediatric and 37% of adult neurologists prescribed either calcium or vitamin D. However, only 9% of pediatric and 7% of adult neurologists prescribed prophylactic calcium or vitamin D for patients receiving AED therapy.

In two parallel, randomized, controlled trials involving 72 adults (18-54 years old) and 78 children and adolescents (10-18 years), Mikati, Fuleihan, et al.[74] investigated the effects of two doses of vitamin D given over 1 year on BMD in ambulatory patients on long-term AED therapy. Adult subjects received either "low-dose vitamin D" (400 IU/day) or "high-dose vitamin D" (4000 IU/day), and children and adolescents received 400 or 2000 IU/day. At baseline, 34% of the adults were in the deficient range of vitamin D levels, and 46% were in the insufficient range; the parallel levels for children were 18% and 44%, respectively. Likewise, using DXA, baseline BMD in adults was lower than that of age-matched and gender-matched controls versus either a Western or an ethnically identical population. After treatment, none of the adults and only a few of the children in the high-dose group still exhibited vitamin D deficiency, and relatively few had vitamin D insufficiency. Furthermore, the authors demonstrated that "significant increases in BMD at all skeletal sites compared to baseline" after 1 year in the high-dose, but not in the low-dose, vitamin D group. Nevertheless, BMD at 1 year remained below normal. Notably, baseline BMD was normal in children (compared with age- and gender-matched controls), and both treatment groups "showed significant and comparable increases" in BMD. The authors concluded that in "ambulatory adults on antiepileptic drugs, high-dose vitamin D therapy substantially increased bone mineral density at several skeletal sites," and that "both doses resulted in comparable increases in bone mass" in children. These findings represent the first clinical trials demonstrating that high-dose vitamin D therapy significantly improves BMD in patients receiving AED therapy.[74]

Report

Duus[75] reported a case of several severe fractures in a patient following epileptic seizures. The patient had epileptic osteomalacia and responded well to vitamin D treatment.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Many individuals with epilepsy, especially children, lead restricted lifestyles and are often institutionalized or under other forms of full-time care. Such individuals not only experience the effects of the pathophysiology on vitamin D metabolism, but also tend to have compromised nutritional status and restricted time outdoors in the sun, especially during winter months. Thus, sunlight represents an effective and low-risk method of supporting vitamin D status. Oral supplementation can also be recommended. A moderate dose of 400 to 1500 IU/day of vitamin D could exert a protective function for individuals using phenobarbital or phenytoin who are concerned about potential drug-induced rickets, osteomalacia, or osteoporosis. Pretreatment and posttreatment monitoring of serum 25-OHD and $1,25\text{-}(OH)_2D$ levels would also identify individuals at risk of treatment-induced and nutritional/sunlight-related deficiencies of vitamin D. Available evidence indicates that such supplementation does not represent a significant risk of interfering with the therapeutic activity of standard anticonvulsant agents. However, as previously suggested, regular exposure to sunlight represents an effective and low-risk method of supporting vitamin D status by providing adequate stimulation of endogenous synthesis of necessary levels of vitamin D. Others have advocated a proactive approach toward the risks of bone loss while voicing caution that given the increased risk of osteomalacia, osteoporosis, and rickets among those taking anticonvulsants, withdrawal from such drugs carries potential for increased risk of seizure-related fractures. Monitoring of bone status is often appropriate.

Bisphosphonates

Evidence: Alendronate (Fosamax), etidronate (Didronel). Extrapolated, based on similar properties: Clodronate (Bonefos, Ostac), ibandronate (Bondronat, Boniva), risedronate (Actonel), tiludronate (Skelid), zoledronic acid (Zometa). Similar properties but evidence lacking for extrapolation: Pamidronate (Aredia).

Effect and Mechanism of Action

The ability of bisphosphonates to inhibit osteoclastic activity and bone resorption, maintain healthy bone mineralization, and produce substantial gains in bone mass depends on the presence of adequate vitamin D and other nutrients (e.g., protein, calcium, phosphorus).[76,77] Calcium, the principal element in bone, can be absorbed in the brush border of the intestinal mucosa only when vitamin D is present. Notably, bisphosphonates have been used effectively to treat the more resistant cases of vitamin D–induced hypercalcemia.

Research

All currently approved, bone-active pharmacological agents have been studied only in conjunction with supplemental calcium, and newer anabolic agents increase mineral demand in skeletal tissue and will thus require even higher levels of calcium repletion.[78] The consensus underlying the fundamental importance of vitamin D and calcium nutriture is underscored by the observation that when Greenspan et al.[79] investigated the relative efficacy of HRT (conjugated estrogen with or without medroxyprogesterone) plus alendronate, HRT alone, alendronate alone, or placebo on spine and hip BMD in 373 osteopenic elderly women, all subjects received calcium and vitamin D supplements. After 3 years, DXA scans showed

that participants taking combination therapy had greater improvement in BMD at the hip and spine than those taking HRT or alendronate alone or taking placebo, all with calcium and vitamin D.

In an uncontrolled clinical trial involving osteoporosis patients with a poor response to bisphosphonate therapy, Heckman et al.[80] found that the addition of 25 μg (1000 IU) per day of vitamin D to the bisphosphonate regimen resulted in significantly increased BMD of the lumbar spine after 1 year. In a randomized, double-blind trial involving 48 osteopenic and osteoporotic women, Brazier et al.[81] compared one group who received 10 mg alendronate once daily along with 500 mg elemental calcium daily and 10 μg (400 IU) cholecalciferol (vitamin D_3) twice daily for 3 months and a second group who received the same dosage of alendronate and calcium but placebo instead of the vitamin D. All subjects had low BMD, serum 25-hydroxyvitamin D_3 (25-OHD, calcifediol) less than 12 μg/L, and dietary calcium intake less than 1 g/day. Although markers of bone remodeling, such as serum and urinary CTX and urinary NTX (C- and N-terminal telopeptides of type I collagen), were dramatically and significantly decreased after as little as 15 days of treatment and remained decreased throughout the course of treatment in both groups, the group also receiving the vitamin D demonstrated a more pronounced effect, particularly after 1 month, for the bone resorption markers serum CTX and urinary NTX. These researchers concluded that coadministration of calcium and vitamin D is appropriate in elderly women with calcium and vitamin D insufficiencies receiving alendronate, to achieve rapid reduction of bone loss.[81]

In a randomized trial involving 154 patients with Crohn's disease, Sifflederen et al.[82] investigated the efficacy of etidronate plus calcium and vitamin D for treatment of low BMD. The subjects, most of whom had T scores in the osteopenic range (−1.5 to −2.5), were administered etidronate (400 mg orally) or placebo for 14 days, and then both groups were given daily calcium (500 mg) and vitamin D (400 IU) for 76 days, in a treatment cycle repeated every 3 months for 2 years. After 24 months, BMD at the lumbar spine, ultradistal radius, and trochanter sites, but not the total hip, increased steadily, significantly, and similarly in both treatment arms. The findings demonstrate that in patients with low BMD on absorptiometry, treatment with calcium and vitamin D alone will increase BMD by about 4% per year, and that adding etidronate to the treatment program does not appear to enhance the effects of calcium and vitamin D.[82] In an accompanying editorial on the preeminence of calcium and vitamin D in limiting fracture risk in Crohn's disease, Bernstein[83] commented that this study provides reassurance that bisphosphonates are "rarely needed in IBD [inflammatory bowel disease] patients, most of whom have T scores greater than −2.5, and many of whom are using corticosteroids to some extent."

Some patients with prostate carcinoma and a diffuse metastatic invasion of the skeleton exhibit indirect biochemical and histological indications of osteomalacia. Bisphosphonates are known to cause symptomatic hypocalcemia in prostate cancer patients with diffuse skeletal metastases. Bisphosphonate administration can aggravate osteomalacia and give the appearance of symptomatic hypocalcemia because of the transient, striking prevalence of osteoblastic activity over bone resorption by osteoclasts, which are inhibited by bisphosphonate drugs. Calcium supplementation is often considered as contraindicated in individuals with prostate cancer. However, concomitant use of calcium with bisphosphonates has been proposed as a means of inhibiting the osteoclastic activation that often precedes the abnormal osteoblastic bone formation within metastases.

In regard to men with nonmetastatic prostate cancer, findings from a small, randomized, double-blind, controlled trial conducted by Nelson et al.[84] showed that treatment with alendronate, 70 mg weekly, plus daily calcium and vitamin D, reversed bone loss in 56 men receiving antiandrogen therapy. In contrast, the 56 subjects taking placebo, calcium, and vitamin D lost bone density during the same period. Notably, among these 112 men, with an average age of 71, only 9% had normal bone mass, whereas 52% had low bone mass and 39% developed osteoporosis after an average 2 years of ADT.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Calcium and vitamin D are essential for maintaining bone mass and density and imperative to the success of drug therapies for inducing bone augmentation.[77] Deficiencies of both nutrients are common in the patient populations at highest risk for osteoporosis. The importance of exercise and sound nutrition (including adequate protein, calcium, and phosphorus intake) as foundational cannot be overemphasized and is supported by growing evidence. Calcium has a clearly demonstrated effect of enhancing estrogen's effects on bone metabolism. Further, most research indicates that consistent exposure to sunlight (excluding winter in northern latitudes) provides a safe and effective, as well as otherwise beneficial, method of elevating vitamin D levels. Doses of 1500 mg calcium and 800 IU vitamin D daily provide prudent nutritional support for osteoporosis prevention and treatment, or more exactly, 30 to 40 mmol calcium with sufficient intake vitamin D daily to maintain serum 25(OH)D levels above 80 nmol/L (~30 μg/L).[78]

Thus, a synergistic combination of oral calcium and vitamin D, within the context of an active lifestyle, constitutes the core proactive intervention within integrative therapeutics for all individuals at high risk for osteoporosis, or a foundational treatment for diagnosed bone loss. Notably, low serum vitamin D levels have been associated with the incidence of falls in older women,[85] and vitamin D has been found to be helpful in reducing the incidence of falls, a major factor in fracture risk, by improving muscle strength, walking distance, and functional ability.[86] Also, hormone supplementation or replacement regimens (conventional HRT, bio-identical estrogens/progesterone, herbal hormone precursors/modulators) should be considered if indicated in women.

In addition to these primary and secondary therapies, a bisphosphonate can provide a potent intervention in reversing bone loss and supporting healthy bone mass. Whereas oral calcium preparations need to be taken at least 2 hours before or after the bisphosphonate to avoid pharmacokinetic interference, such timing of oral vitamin D intake is unnecessary because no evidence has indicated potential pharmacological interference with bisphosphonates or other components of the treatment. It is generally recommended that alendronate or etidronate be taken with a full glass (6-8 ounces) of plain water on an empty stomach, avoiding the recumbent position for at least 30 minutes to prevent the potential for severe esophageal irritation associated with incomplete transfer of the tablet to the stomach.

Calcitriol and Vitamin D Analogs

Alfacalcidol, calcitriol, dihydrotachysterol.

See also later discussion for therapeutics involving vitamin D analogs and other agents.

Interaction Type and Significance

✗✗ Minimal to Mild Adverse Interaction—Vigilance Necessary

✗✗✗ Potentially Harmful or Serious Adverse Interaction—Avoid

◇◇ Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate

Probability: 1. Certain

Evidence Base: ● Consensus

Effect and Mechanism of Action

The simultaneous use of supplemental vitamin D and vitamin D analogs, such as calcitriol, inherently produces an additive effect. The potential for vitamin D toxicity is particularly increased because calcitriol [$1,25(OH)_2D_3$] and its drug formulations bypass physiological feedback mechanisms and control systems that normally limit its production in the kidneys. The clinical significance and severity of the interaction primarily depend on the respective dosages involved and duration of intake, although individual variability based on VDR genotype, diet, and other factors may modify the intensity and character of the response.

Research

Research into coordinated administration of supplemental vitamin D and vitamin D analogs represents a viable approach to integrative therapeutics that has yet to be conducted in a systemic manner.

The use of calcitriol and other vitamin D analogs in combination with other pharmaceutical agents represents an emerging area of therapeutic synergy. Even though these agents are drugs and not nutrients per se, their action is derived from their relationship to vitamin D, and their therapeutic application is discussed briefly later.

Reports

Reports of vitamin D toxicity resulting from simultaneous intake of vitamin D and pharmaceutical analogs are lacking.

Clinical Implications and Adaptations

Coadministration of vitamin D and analogs such as calcitriol may be appropriate in some circumstances, as in renal disease, but only under close medical supervision. Unintentional concomitant use of vitamin D and its pharmacological analogs should be avoided through direct inquiry by health care providers of patients initiating therapy and routine implementation of a thorough inventory of vitamin and other supplement intake.

Cholestyramine, Colestipol, and Related Bile Acid Sequestrants

Evidence: Cholestyramine (Locholest, Prevalite, Questran), colestipol (Colestid).
Extrapolated, based on similar properties: Colesevelam (WelChol).

Interaction Type and Significance

≈≈≈ Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management

◇ Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern

Probability: 4. Plausible

Evidence Base: ○ Preliminary

Effect and Mechanism of Action

Absorption of dietary sources of vitamin D requires bile. Bile acid sequestrants, such as cholestyramine and colestipol, decrease lipid digestion and absorption. In the process, they also reduce absorption of the fat-soluble vitamins, such as vitamin D, and other nutrients.[87-89]

Research

Tonstad et al.[90] conducted a study of 37 boys and 29 girls age 10 to 16 years with familial hypercholesterolemia, first in an 8-week, double-blind, placebo-controlled protocol, then in open treatment for 44 to 52 weeks. After 1 year of colestipol, those who took 80% or more of the prescribed dose had a greater decrease in serum 25-OHD levels than those who took less than 80%. They also found that levels of serum folate, vitamin E, and carotenoids were reduced in the colestipol group.[90]

In a rodent model, Watkins et al.[91] found that cholestyramine may deplete calcium (and zinc), an effect that could adversely impact the function of vitamin D, especially in regard to bone health.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Fat-soluble vitamins, and vitamin D nutriture in particular, can play a valuable role in the prevention and treatment of many conditions involving the cardiovascular system and lipid metabolism (including atherosclerosis, heart disease, obesity, hypertension, and diabetes), such that interference with its absorption could be counterproductive in relation to the broad therapeutic strategy and clinical outcomes. Modest supplementation with vitamin D (10-20 µg or 400-800 IU daily) may be advisable for many individuals, particularly those at high risk for deficiency sequelae, but consistent exposure to sunlight (without sunscreen) may be sufficient to maintain healthy vitamin D levels and can be combined with the exercise usually critical to those prescribed bile acid sequestrants. Exposure to sunlight in the winter months of higher latitudes, however, is likely to be insufficient to maintain adequate vitamin D levels, making dietary use of supplements or a rich natural source of vitamin D (e.g., cod liver oil) necessary, separated from the bile acid sequestrant by at least 2 hours.

Cimetidine

Cimetidine (Tagamet)

Interaction Type and Significance

≈≈≈ Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management

◇ Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern

Probability: 4. Plausible

Evidence Base: ○ Preliminary

Effect and Mechanism of Action

Cimetidine inhibits vitamin D hydroxylase (a hepatic mixed-function oxidase) and may reduce hepatic activation of vitamin D through hydroxylation.[92]

Research

In limited animal and human research, cimetidine has been found to decrease the synthesis of vitamin D and adversely affect serum levels of 25-OHD.

In a small, uncontrolled trial, Odes et al.[93] treated nine adult subjects with 400 mg cimetidine orally twice daily

during a period from winter to summer, as the daily duration of sunlight was increasing. They measured serum levels of 25-OHD, 24,25$(OH)_2$D, and 1,25$(OH)_2$D before treatment, after 4 weeks of treatment, and 1 month after cessation of treatment. The normal seasonal increase in the level of 25-OHD was not observed during treatment. However, 25-OHD did rise significantly after the cimetidine was withdrawn. These researchers concluded that their findings "suggest that short-term treatment with cimetidine could potentially perturb vitamin D metabolism in man."

Further clinical trials would be necessary confirm these preliminary findings and to determine whether other H_2 receptor antagonists might similarly affect vitamin D metabolism in humans.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Laboratory tests can determine blood levels of 25-hydroxycholecalciferol, the form of vitamin D after it has been hydroxylated in the liver. Low levels require prescription of an activated form of vitamin D (e.g., calcitriol) because activation of a regular vitamin D supplement (or even cholecalciferol derived from sunlight exposure) would be vulnerable to blockage by the cimetidine. In this case it would be prudent to monitor the serum level of 1,25-dihydroxyvitamin D to be certain that replacement is adequate but not excessive.

Corticosteroids, Oral, Including Prednisone

Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol) prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).

Similar properties but evidence indicating no or reduced interaction effects: Inhaled or topical corticosteroids.

Interaction Type and Significance

Evidence Base: **○ Emerging**

Effect and Mechanism of Action

Oral corticosteroids are associated with osteoporosis. The mechanism is multifactorial, including reduced calcium absorption, decreased vitamin D availability, lowered serum 25-hydroxycalciferol levels, and interference with vitamin D activation and metabolism, all increasing risk of bone loss.[94-99] Corticosteroids also contribute to osteoporosis through increased renal calcium excretion and decreased bone formation by osteoblasts and serum levels of sex hormones. Administration of cortisone impairs net calcium absorption through two mechanisms: depressed vitamin D–dependent calcium absorption and increased vitamin D–independent calcium backflux.[100]

Research

It is generally recognized that long-term use of corticosteroids can lead to loss of bone mineral density (BMD) and higher risk for fractures. Of patients using corticosteroids for long periods, 25% develop at least one fracture. Although the usefulness of calcium and vitamin D supplements in the treatment and the prevention of steroid-induced osteoporosis may seem self-evident, research into the effectiveness of such nutritional therapies has been slow to evolve. Nevertheless, it now appears that the adverse effects of glucoactive corticosteroids on intestinal calcium transport and bone turnover can usually be counteracted by the combined administration of supplemental doses of calcium and physiological doses of 25-OHD_3.

In 1977, Hahn et al.[101] observed no significant serum 25-OHD concentrations in 21 adults receiving chronic, moderate-dose corticosteroid therapy and who demonstrated radiological osteopenia (vs. controls). However, in 1978, Chesney et al.[98] found a reduction of serum 1,25$(OH)_2$D in children receiving long-term glucocorticoid treatment for various glomerular diseases (vs. children with chronic glomerulonephritis but not treated with glucocorticoids). They further observed that this reduction in serum 1,25$(OH)_2D_3$ concentration correlated with the dose of steroid administered as well as with the severity of reduction in forearm bone mineral content.

By administering 20 mg/day of prednisone to 12 normal adults for 14 days, Hahn et al.[94] confirmed that glucocorticoids suppress intestinal calcium absorption (by 31%), but not by decreasing circulating concentrations of biologically active vitamin D metabolites, since mean serum concentrations of 25-OHD and 24,25$(OH)_2$D did not change significantly from initial values; serum 1,25$(OH)_2$D concentration was even slightly increased.

In a 2-year, randomized, double-blind, placebo-controlled trial, Buckley et al.[102] administered 500 IU of vitamin D_3 and 1000 mg of calcium carbonate daily to 65 rheumatoid arthritis patients being treated with low amounts of prednisone (mean dosage, 5.6 mg daily). They found that those who received the nutrients maintained or gained BMD in the lumbar spine and trochanter, whereas those receiving prednisone therapy but were given placebo (i.e., no supplements) lost BMD in the same areas during the course of the study. In a subsequent study (1998), Lems et al.[103] reported that low-dose (10 mg/day) prednisone (LDP) treatment led to a decrease in osteocalcin, P1CP, and alkaline phosphatase and an increase in urinary excretion of calcium. They concluded that LDP has a negative effect on bone metabolism because bone formation decreased while bone resorption remained unchanged or decreased slightly. They also found parathyroid hormone (PTH) increased (insignificantly) during LDP (+19%) and LDP plus calcium (+14%), but decreased during coadministration of with calcitriol (−16%) and calcium/calcitriol (−44%). The increase in PTH during LDP could be prevented by calcitriol combined with calcium supplementation.

Wissing et al.[104] conducted a 1-year controlled trial investigating the effect of low-dose corticosteroids on post–renal transplant bone loss and the ability of cholecalciferol to further decrease bone loss. They administered either 400 mg oral calcium or 400 mg oral calcium daily in association with a monthly dose of 25,000 IU vitamin D_3 to 90 patients admitted for renal transplantation and scheduled to be treated with low doses of prednisolone. All subjects experienced a "moderate but significant" loss of lumbar spine BMD, but no bone loss at the femoral neck and shaft during the first posttransplant year. Subjects in the calcium/D_3 group had significantly higher 25-OHD but not 1,25$(OH)_2$D levels and exhibited slightly higher bone loss, but the difference did not reach statistical significance. The researchers also reported "a highly significant negative correlation between 25(OH) vitamin D and intact parathyroid

hormone (iPTH) serum levels." They concluded that "cholecalciferol supplementation did not prevent posttransplant bone loss but contributed to the normalization of iPTH levels after renal transplantation."[104] Notably, the dose administered, 25,000 IU of D_3 once a month, is less than the 1000 IU per day recommended by experts as the minimum for those not exposed to adequate sunlight, and it is not well timed for an agent with a half-life of 2 weeks.

A meta-analysis of well-designed clinical trials by Amin et al.[105] concluded that supplementation with vitamin D and calcium was more effective than placebo or calcium alone in providing a "moderate" protective effect against corticosteroid-induced osteoporosis, using change in lumbar spine BMD as the primary outcome measure. However, bisphosphonates and fluoride were more effective than vitamin D in some trials.

In contrast, numerous studies and several reviews of inhalant and nasal corticosteroids have consistently concluded that such medications, in and of themselves, do not generally pose a significant risk of inducing bone loss in children or adults.[106] For example, Elmstahl et al.[107] reported no difference in BMD in a group of subjects taking inhaled corticosteroids and unexposed control subjects, nor was any dose-response relationship observed between inhalant steroid therapy and BMD. Likewise, Suissa et al.[108] conducted a case-control study nested within a population-based cohort of all Quebec patients at least 65 years of age who were given respiratory medications and followed for at least 4 years. The rate of fracture for current inhaled corticosteroid use was not increased, and the rate of upper extremity fracture increased by 12% (RR 1.12) with every 1000-µg increase in the daily dose of inhaled corticosteroids. No such increase was observed for hip fracture. Among a subgroup of subjects followed more than 8 years, "only the use of more than 2000 µg of inhaled corticosteroids per day for an average of 6 years was associated with an elevated risk of fracture." No increase in the rate of fractures was observed at any dose of nasal corticosteroids.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing corticosteroids, possibly for only 1 month but especially for longer periods, are advised to discuss the potential adverse metabolic implications of such medications with patients and compensatory options. In 1998, Lems et al.[109] noted that "in spite of guidelines according to which patients protractedly using corticosteroids should take sufficient calcium and cholecalciferol, only about one-tenth of them takes any form of medication to prevent osteoporosis." Most research indicates that calcium intakes from dietary and supplemental sources totaling 1000 to 1500 mg of calcium per day in conjunction with 10 to 20 µg (400-800 IU) of vitamin D are required to prevent adverse effects, although much higher doses may be necessary in the context of a preexisting 25OHD deficiency.[40] Monitoring serum levels of both 25-OHD and $1,25(OH)_2D$ (activated form of vitamin D) is appropriate, and supplementation (or possibly a prescription of calcitriol) is often necessary if a deficiency is indicated. If 25-OHD levels are low (< 50 nmol/L), correction with up to 7000 IU vitamin D_3 per day, or 50,000 IU vitamin D_2 per week, for 1 to 2 months will correct the $1,25(OH)_2D$ level in patients with normal renal function. Often the $1,25(OH)_2D$ (dihydroxycholecalciferol) level is maintained, even in the face of a 25-OHD deficiency, due to increased secretion of PTH, which speeds up renal conversion of 25-OHD to the active form. Thus, measuring intact PTH, as well as both forms of vitamin D, provides the most complete picture of vitamin D status.[40] It is also prudent to monitor for hypercalciuria and hypercalcemia when supplementing with both calcium and vitamin D, although the occurrence of hypercalcemia is rare.

Physicians prescribing steroids for longer than 2 weeks should encourage all patients to modify their lifestyles, including smoking cessation and limitation of alcohol consumption. The importance of mild to moderate weight-bearing exercise cannot be overemphasized; 30 minutes to 1 hour every day, particularly with sunlight exposure, should be strongly encouraged, if feasible. However, individuals with known or potential bone loss should be advised to develop an exercise program under the supervision of a physician or other health care professional familiar with the increased risks of fracture associated with long-term use of steroids.

Some physicians may consider it necessary and appropriate to prescribe calcitriol in individual cases. Concomitant use of bisphosphonates and estrogen/progesterone support may also be appropriate for some individuals using oral steroids longer than 3 months, especially if low BMD is evident or likely.

Hormone Replacement Therapy (HRT): Estrogen-Containing and Synthetic Estrogen and Progesterone Analog Medications

Evidence: HRT, estrogens: Chlorotrianisene (Tace); conjugated equine estrogens (Premarin); conjugated synthetic estrogens (Cenestin); dienestrol (Ortho Dienestrol); esterified estrogens (Estratab, Menest, Neo-Estrone); estradiol, topical/transdermal/ring (Alora Transdermal, Climara Transdermal, Estrace, Estradot, Estring FemPatch, Vivelle-Dot, Vivelle Transdermal); estradiol cypionate (Dep-Gynogen, Depo-Estradiol, Depogen, Dura-Estrin, Estra-D, Estro-Cyp, Estroject-LA, Estronol-LA); estradiol hemihydrate (Estreva, Vagifem); estradiol valerate (Delestrogen, Estra-L 40, Gynogen L.A. 20, Progynova, Valergen 20); estrone (Aquest, Estragyn 5, Estro-A, Estrone '5', Kestrone-5); estropipate (Ogen, Ortho-Est); ethinyl estradiol (Estinyl, Gynodiol, Lynoral).

HRT, estrogen/progestin combinations: Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); conjugated equine estrogens and norgestrel (Prempak-C); estradiol and dydrogesterone (Femoston); estradiol and norethindrone, patch (CombiPatch); estradiol and norethindrone/norethisterone, oral (Activella, Climagest, Climesse, FemHRT, Trisequens); estradiol valerate and cyproterone acetate (Climens); estradiol valerate and norgestrel (Progyluton); estradiol and norgestimate (Ortho-Prefest).

Related but evidence lacking for extrapolation: HRT, estrogen/testosterone combinations: Esterified estrogens and methyltestosterone (Estratest, Estratest HS).

HRT, progestins: Dydrogesterone (Duphaston), intrauterine L-norgestrel system (Mirena), medroxyprogesterone acetate (Provera), norethisterone (norethindrone; Micronor).

HRT, progesterone: Micronized progesterone (Prometrium, Utrogestan).

Medroxyprogesterone: Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); medroxyprogesterone, oral (Cycrin, Provera); medroxyprogesterone, injection (depot medroxyprogesterone acetate, DMPA; Depo-Provera, Depo-subQ Provera 104); progestin and estrogen injectable: estradiol cypionate and medroxyprogesterone acetate (Cyclofem, Lunelle).

Interaction Type and Significance

○ **Emerging**

Effect and Mechanism of Action

The combination of vitamin D and estrogen replacement therapy (ERT, in the context of calcium supplementation) increases bone mass more than ERT alone, especially in osteoporotic women. The ability of exogenous female hormones, particularly forms of estrogen, to effectively inhibit osteoclastic activity and bone resorption, maintain healthy bone mineralization, and support bone mass is inherently dependent on the presence of vitamin D and other nutrients (e.g., protein, calcium, phosphorus).[76,77] Calcium, the principal element in bone, can be absorbed in the brush border of the intestinal mucosa only when vitamin D is present. Estrogen appears to have a beneficial effect on vitamin D (and calcium) metabolism, although progestins may diminish that benefit. Estrogen also inhibits osteoclastic action, which would represent an additive interaction with vitamin D.

Research

The negative calcium balance usually associated with aging is accentuated in osteoporotic women who have decreased calcium absorption and decreased serum levels of $1,25(OH)_2D$. In a controlled trial involving 17 women with surgically induced menopause, Lobo et al.[110] (1985) observed that serum levels of $1,25(OH)_2D$ increased and urinary calcium loss decreased after 2 months of conjugated estrogens (0.625 mg daily).[110] Subsequently, several studies have investigated various aspects of the question of whether such elevated vitamin D levels might correspond with increased bone strength and reduced risk of fractures and how this effect might vary given initial BMD status, for different individuals, under different HRT regimens, or with different forms of calcium.

Several studies have examined the role of HRT in improving vitamin D activity and calcium balance in women with postmenopausal osteoporosis. In an early study of postmenopausal women by Bikle et al.,[111] treatment with 17β-estradiol alone increased serum $1,25(OH)_2D$, but the addition of medroxyprogesterone, a progestin, lowered vitamin D levels such that total and free $1,25(OH)_2D$ returned toward baseline and thus appeared to antagonize part of the beneficial effects on calcium homeostasis attributable to estrogen. In the first prospective trial confirming the beneficial effect of HRT on prevention of peripheral fractures in nonosteoporotic postmenopausal women and subsequent controlled studies, Komulainen et al.[112-114] determined that supplementation with 300 IU/day of vitamin D_3 (cholecalciferol) does not prevent bone loss in healthy, nonosteoporotic, early-postmenopausal women, nor does such low-dose vitamin D_3 provide significant benefit beyond that attributable solely to combined estradiol and progestin. However, in a 4-year, prospective, partly randomized study of 60 osteoporotic women, Tuppurainen et al.[115] found that vitamin D_3 (cholecalciferol, 300 IU/day, no intake during June–August) together with a combination of 2 mg estradiol valerate and 1 mg of a progestin (cyproterone acetate) daily resulted in greater improvement in BMD compared with estradiol/progestin alone (as well as with baseline or placebo). The osteoporotic women in both HRT groups demonstrated a significant increase in lumbar BMD, but there were no statistically significant differences in either lumbar or femoral BMD changes between these two HRT groups. Furthermore, the combination of HRT and vitamin D_3 was associated with a greater increase in femoral neck BMD than with HRT alone.

In a randomized, double-blind, placebo-controlled trial involving 128 healthy Caucasian women over age 65 with low spinal BMD, Recker et al.[116] compared parameters of BMD and bone loss under continuous low-dose HRT (conjugated equine estrogen, 0.3 mg/day, and medroxyprogesterone, 2.5 mg/day) in conjunction with calcium and vitamin D supplementation versus placebo. Subjects in both groups were administered sufficient calcium supplementation to bring all calcium intakes above 1000 mg/day and oral 25-OHD sufficient to maintain serum 25-OHD levels of at least 75 nmol/L. Through the course of 3.5 years of observation, significant increases were seen in spinal BMD as well as in total-body and forearm bone density, particularly among patients with greater than 90% adherence to therapy. Meanwhile, breast tenderness, spotting, pelvic discomfort, mood changes, and other symptoms typically associated with HRT were mild and short-lived under this relatively low-dose regimen. These authors concluded that "continuous low-dose HRT with conjugated equine estrogen and oral medroxyprogesterone combined with adequate calcium and vitamin D provides a bone-sparing effect that is similar or superior to that provided by other, higher-dose HRT regimens in elderly women" and is well tolerated by most patients.[116]

In a 6-month, placebo-controlled clinical trail involving 21 postmenopausal women with osteoporosis, Gallagher et al.[117] observed that conjugated equine estrogen increased both calcium absorption and serum vitamin D levels [$1,25(OH)_2D$]. Subsequently, these researchers investigated the roles of estrogen deficiency and declining calcium absorption from reduced activated vitamin D (calcitriol) levels or intestinal resistance to calcitriol as central factors in age-related bone loss. In a randomized, double-blind, placebo-controlled trial involving 485 elderly women (66-77 years old) with normal BMD for their age, Gallagher et al.[118] compared the effects of ERT (0.625 mg conjugated estrogens daily for women without a uterus) and HRT (ERT plus 2.5 mg medroxyprogesterone acetate daily for those women with a uterus) with or without calcitriol (1,25-OHD) versus placebo. Hormone therapy alone and in combination with calcitriol were both highly effective in reducing bone resorption and increasing BMD at the hip and other key sites. In particular, calcitriol was effective in increasing BMD in the femoral neck and spine. The combination of ERT/HRT and calcitriol increased BMD in the total hip and trochanter significantly more than did ERT or HRT alone, particularly in women adherent to treatment. Thus, the concomitant use of vitamin D, calcium, and conventional forms of HRT appear generally to raise vitamin D levels but especially to enhance BMD in women who demonstrate osteoporosis, that is, those for whom BMD is most critical. Furthermore, such nutritional support may also allow for reduced HRT dosages and corresponding decrease in risk of attendant adverse effects and sequelae.

The form of calcium used for supplementation presents a potential confounding factor that has not been considered by most researchers but that would be a central concern to most practitioners of nutritional therapeutics. By examining data from a trial involving 25 postmenopausal women, Heller et al.[119] (2002) found that variable results of reported calcium supplementation studies may be caused by the effects of estrogen treatment or vitamin D status on the bioavailability of calcium citrate versus calcium carbonate. Using data derived from a prior trial in 25 postmenopausal women, the authors found that change in area under the curve (ΔAUC) of serum calcium after subtraction of placebo was significantly higher

after calcium citrate than after calcium carbonate in non-estrogen-treated patients. Estrogen-treated patients showed no evident difference in the bioavailability of calcium between the two calcium formulations. Bioavailability was also significantly higher with the citrate salt for the subgroups with lower serum 25-OHD and higher serum $1,25(OH)_2D$ concentrations. Thus, bioavailability of calcium from calcium carbonate was more dependent on estrogen treatment and vitamin D status than that of calcium citrate.

Preliminary research into polymorphisms of the estrogen receptor (ER), vitamin D receptor (VDR), and their interactions may help clarify individual genetic variations in the influence of hormone therapies, exercise, ethnic background, and other factors on bone mineral density (BMD) and peak bone mass. In a population-based, 3-year, longitudinal study of BMD, Willing et al.[120] found that two genetic ER polymorphisms were significantly predictive of both lumbar spine and total-body BMD level, but not change in BMD during the study. A genetic VDR variant was not associated with baseline BMD, change in BMD over time, or any of the bone-related serum and body composition measurements in the 372 women in whom it was evaluated. Further, no other polymorphic markers were identified as being significantly associated with BMD measurements. However, these researchers did identify a significant impact on BMD levels associated with an interaction of two ER polymorphisms and two VDR genotypes. Subjects who had the (−/−) PvuII ER and bb VDR genotype combination had a very high average BMD, whereas women with the (−/−) PvuII ER and BB VDR genotype had significantly lower BMD levels. Differences in serum levels of osteocalcin, PTH, $1,25(OH)_2D$, or $25(OH)_2D$ did not explain this contrast. These authors concluded that their findings "suggest that genetic variation at the ER locus, singly and in relation to the vitamin D receptor gene, influences attainment and maintenance of peak bone mass in younger women, which in turn may render some individuals more susceptible to osteoporosis than others."[120]

Subsequently, in a study involving 108 postmenopausal Caucasian women, Deng et al.[121] found that VDR and ER genotypes may have different effects on BMD at different sites and on total-body bone mineral content (tbBMC). They assessed associations of BMD with VDR BsmI genotypes and ER XbaI (ERX) and PvuII (ERP) polymorphisms with spine, femoral neck, and distal radius BMD and with tbBMC. In this sample, researchers did not detect a significant association for ER genotypes with spine and radius BMD, or for VDR genotypes with femoral neck and radius BMD and tbBMC, or find a significant interaction between VDR and ER genotypes. However, they did note significant associations between (1) VDR genotypes and spine BMD variation, (2) both ERX and ERP genotypes and femoral neck BMD variation, and (3) ERX genotypes and tbBMC variation. Based on these observations, these researchers concluded that "if significant factors influencing bone are not appropriately controlled, true significant associations can easily be missed."[121] Related research suggests that bone may be more responsive to exercise in some genotypes of VDR than in others,[1] and that gene-environment interactions such as leisure physical activity and VDR genotype may play a role in maintaining the BMD at the lumbar spine in active postmenopausal women, especiallyolder women.[2]

The importance of individual genotypes as important factors in determining changes in bone mass in the elderly, with and without HRT, as well as other factors, such as vitamin D and mineral nutriture and exercise, is becoming increasingly clear and will undoubtedly receive greater consideration in shaping individualized therapeutic strategies to optimize and preserve bone mass.

Myrup et al.[122] cautioned against a possible limiting effect of cholecalciferol on the lipid benefits of HRT, along with potential risk of hypercalcemia. In a double-blind, randomized trial involving 74 postmenopausal women, they investigated the effect of cholecalciferol and estrogen-norethindrone treatment for 1 year on total cholesterol level, high-density lipoprotein (HDL) cholesterol level, blood pressure, and body mass index. A similar decrease in serum cholesterol level was demonstrated in subjects receiving estrogen-norethindrone (11%) and those receiving hormones combined with cholecalciferol (13%); this hypocholesterolemic effect was most pronounced in lean women. However, the HDL cholesterol/total cholesterol ratio increased only 25% in women administered both estrogen-norethindrone and cholecalciferol, versus an increase of 45% with estrogen-norethindrone treatment alone.[122] Subsequently, in a in a population-based, prospective, 3-year study involving 464 women, Heikkinen et al.[123] arrived at similar conclusions. They found that serum concentrations of HDL cholesterol did not change significantly in the group receiving HRT (sequential combination of 2 mg estradiol valerate and 1 mg cyproterone acetate) alone, but decreased in the groups receiving vitamin D_3, HRT plus vitamin D_3, or placebo.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Hormone support, calcium, and vitamin D act in concert to enhance the primary activities of nutrition and exercise in healthy bone metabolism. HRT has been the mainstay of osteoporosis prevention but is limited because of dose-related risks, adverse effects, and patient acceptance. Furthermore, because estrogen alone can be safely used only in women without a uterus, due to an unacceptably high incidence of uterine cancer with unopposed estrogen, all postmenopausal women with an intact uterus receiving hormonal therapy must be treated with some combination of estrogen and progestins or their analogs, even though estrogen's effect on bone appears potentiated by calcium and vitamin D, and progestins may work against it. Calcium and vitamin D are essential for maintaining bone mass and density and imperative to the success of drug therapies for inducing bone augmentation.[77] Deficiencies of both nutrients are common in the patient populations at highest risk for osteoporosis. The importance of exercise and sound nutrition (including adequate protein and phosphorus intake) as foundational cannot be overemphasized and is supported by growing evidence.[2,124,125]

Calcium and estrogen have a clearly demonstrated synergistic effect of enhancing each other's effects on bone metabolism. Further, most research indicates that consistent exposure to sunlight provides a safe and effective, as well as otherwise beneficial, method of elevating vitamin D levels. Nevertheless, prudent nutritional support for osteoporosis prevention and treatment can be provided through diet or supplementation including 1500 mg/day of calcium and 800 IU (20 μg) vitamin D, or more exactly, sufficient intake vitamin D per day to maintain serum 25(OH)D levels above 80 nmol/L.[78]

Thus, a synergistic combination of oral calcium and vitamin D, within the context of an active lifestyle, constitutes the core proactive intervention within integrative therapeutics for all individuals at high risk for osteoporosis, or a base treatment for diagnosed bone loss. Additionally, hormone supplementation or replacement regimens (conventional HRT, bio-identical estrogens/progesterone, isoflavones, herbal

hormone precursors/modulators) may produce the same effects, but conclusive evidence is lacking. Further research through well-designed clinical trials is warranted.

Although exogenous hormone therapy (and possibly understudied/untested "natural" alternatives) appears to enhance vitamin D metabolism, the importance of consuming adequate levels of vitamin D through diet and supplements cannot be overstated while taking hormones. As indicated by some of the research reviewed, total cholesterol, low-density lipoprotein (LDL) cholesterol, and HDL cholesterol ratios deserve monitoring in the event that vitamin D supplementation might exert a dyslipidemic effect. Again, exercise might be indicated as playing a fundamental role in the comprehensive therapeutic approach. Notably, low serum vitamin D levels have been associated with the incidence of falls in older women,[85] and vitamin D has been found to be helpful in reducing the incidence of falls, a major factor in fracture risk, by improving muscle strength, walking distance, and functional ability.[86] Overall, further research is needed to determine the character and full implications of the interaction(s) between supplemental vitamin D and exogenous hormone therapy and their relationship to the many factors influencing bone health and the risks of osteoporosis and fractures.

Heparin, Unfractionated

Heparin, unfractionated (Calciparine, Hepalean, Heparin Leo, Minihep Calcium, Minihep, Monoparin Calcium, Monoparin, Multiparin, Pump-Hep, Unihep, Uniparin Calcium, Uniparin Forte).

Interaction Type and Significance

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Over time, heparin causes bone loss, especially in the spine, hips, pelvis, and legs. This effect is more pronounced with standard (unfractionated) heparin (UFH) than with low-molecular-weight heparin (LMWH). At least one mechanism of the negative effect of UFH on bone is nonspecific binding of the longer polysaccharide chains to bone, with inhibition of osteoblastic function. Heparin may also inhibit formation of 1,25-dihydroxyvitamin D by the kidneys.[126]

Research

Majerus et al.[127] reported that use of heparin, at high doses, for several months causes osteoporosis. Likewise, both Wise and Hall[128] and later Haram et al.[129] found that women who received heparin therapy during pregnancy experienced decreased bone density (i.e., osteopenia). On the other hand, in one study, nine women on heparin treatment received 6.46 g daily of a special calcium preparation, osscin-hydroxyapatite compound (OHC) for 6 months and were compared to 11 women not receiving the bone-protective treatment. In the OHC group, good compliance was observed, with no side effects and reduced back pain. Those taking the calcium preparation did not demonstrate the expected decrease in bone mass, and bone mass decreased significantly in the controls.[130]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although the adverse effects of heparin on vitamin D and bone metabolism are well documented, research confirming the benefits of supplementing vitamin D and calcium in individuals on heparin therapy for any extended period is limited. However, in the meantime, such nutritional support would most likely be beneficial and is not contraindicated. Physicians prescribing UFH may find it prudent to coadminister with calcium and vitamin D supplementation. With chronic use, the vitamin D metabolite that should be measured to determine vitamin D status is 25(OH)D (25-hydroxyvitamin D), which is the major circulating form of vitamin D, circulating at 1000 times the concentration of $1,25(OH)_2D$ (1,25-dihydroxyvitamin D) and having a half-life of 2 weeks; after D_3 repletion has been initiated, monitoring $1,25(OH)_2D$ may be adequate. In some cases, if low, calcitriol may be necessary and appropriate to restore normal activated vitamin D levels; calcitriol is usually required (or appropriate) only in those patients unable to convert 25(OH)D to calcitriol. With long-term heparin therapy, assessment and monitoring of BMD may also be indicated.

Isoniazid and Related Antitubercular Agents

Isoniazid (isonicotinic acid hydrazide, INH; Laniazid, Nydrazid); combination drugs: isoniazid and rifampicin (Rifamate, Rimactane); isoniazid, pyrazinamide, and rifampicin (Rifater). Extrapolated, based on similar properties: Cycloserine (Seromycin), ethambutol (Myambutol), ethionamide (2-ethylthioisonicotinamide; Ethide, Ethiocid, Ethomid, Etomide, Mycotuf, Myobid, Trecator SC), pyrazinamide (PZA; Tebrazid).

See also Rifampin.

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Research indicates that antituberculous drugs, including isoniazid (INH), induce vitamin D deficiency. Vitamin D levels have been found to be lowered in children with tuberculosis (TB), both in untreated children and in those taking isoniazid. Observed declines in activated vitamin D ($1\alpha,25$-dihydroxyvitamin D) can produce relative hypocalcemia and induce elevation in PTH levels. Isoniazid can inhibit hepatic mixed-function oxidase activity, as evidenced by a reduction in antipyrine and cortisol oxidation, as well as hepatic 25-hydroxylase and renal 1α-hydroxylase; thereby causing such a reduction in the corresponding vitamin D metabolites.[131,132]

Research

Brodie et al.[131] investigated the effect of isoniazid on vitamin D metabolism, serum calcium and phosphate levels, and hepatic monooxygenase activity by administering isoniazid, 300 mg daily, to eight healthy subjects for 14 days. They observed several responses, including a 47% drop in the concentration of $1\alpha,25(OH)_2D$ (the most active metabolite of vitamin D) after a single dose of isoniazid, with lowered levels continuing throughout the study; declines in levels of 25OHD (the major circulating form of the vitamin) in all subjects and to below normal range in six; and a 36% elevation in PTH levels in response to the relative hypocalcemia produced. In a study

involving 46 children with asymptomatic TB, Toppet et al.[133] found that children administered isoniazid for 3 months demonstrated a decrease in blood levels of $1,25(OH)_2D$. Isoniazid appears to interfere similarly with the activity of many other nutrients, including magnesium.

Specific evidence is lacking to determine if isoniazid or related agents actually cause symptoms of vitamin D deficiency and calcium depletion, especially with long-term therapy. Clinical trials are warranted to investigate the clinical significance of any depletion pattern and efficacy of prophylactic intervention. Such research is particularly important in children undergoing long-term therapy, in whom potential adverse effects may significantly impair the calcium economy during this critical life stage, when maximum bone density is being attained and will be relied on for life.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing isoniazid or related antitubercular therapy, especially for longer than 1 month, are advised to recommend coadministration of vitamin D and calcium, preferably as part of a multivitamin and mineral formulation (at least 50 mg vitamin B_6 daily is indicated with INH as well); this prudent measure is unlikely to interfere with the efficacy of the medication(s). Vitamin D supplementation may be of great value in addition to antituberculous drugs in the treatment of tuberculous children, and its use is highly recommended.[134] Exposure to sunlight is the simplest and most natural way to provide activated vitamin D; sunshine and mountain air were characteristic of the great TB sanitoriums in the pre–anti-TB drug era. However, when vitamin D is to be supplemented orally, the typical dosage would be in the range of 5 to 10 µg (200-400 IU) per day, depending on size and body weight. Concurrent calcium supplementation in the range of 100 to 250 mg three times daily would be appropriate, but research is lacking to confirm specific effective dosage levels.

Granulomatous lesions, such as those present in extensive TB infection, often contain active 1-hydroxylase enzymes that activate 25-OH-cholecalciferol and are independent of the feedback mechanisms that regulate the renal 1-hydroxylase enzymes. Regular monitoring of serum calcium would reveal early vitamin D toxicity in this setting. Research findings emphasize the need for regular monitoring of 25(OH)D and bone status in this population, even if no sign of rickets is observed in these patients.

Ketoconazole

Ketoconazole (Nizoral).

Interaction Type and Significance

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Ketoconazole blocks adrenal steroidogenesis by inhibiting P450 enzymes involved in steroid hormone synthesis. In so doing, however, ketoconazole also inhibits 1α-hydroxylase and 24-hydroxylase, the P450 enzymes that metabolize vitamin D; inhibits renal $1,25(OH)_2D$ synthesis; and reduces serum levels of calcitriol.[135,136]

This activity enables ketoconazole to serve as a second-line ADT in the treatment of prostate cancer. The ability of vitamin D to inhibit growth of prostate cancer cells depends on levels of the active metabolite, $1,25(OH)_2D$ (calcitriol). Because 24-hydroxylase converts calcitriol to less active products, its inhibition by ketoconazole maintains the magnitude and duration of response to calcitriol.[137]

Research

Adams et al.[138] reported that ketoconazole decreases the serum $1,25(OH)_2D$ and calcium concentration in sarcoidosis-associated hypercalcemia. In several studies, Glass et al.[139-141] found that ketoconazole reduced previously elevated serum $1,25(OH)_2D$ and total serum calcium in hypercalcemic patients, particularly those with sarcoidosis. In a study of 19 patients with well-characterized absorptive hypercalciuria, Breslau et al.[142] found they could separate subjects into those who responded to ketoconazole and those who were nonresponders. Responders demonstrated reduced serum $1,25(OH)_2D$, decreased intestinal calcium absorption, and decreased 24-hour urinary calcium excretion.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing ketoconazole for extended periods, including use in conjunction with calcitriol for the treatment of prostate cancer, are advised to closely supervise and regularly monitor for drug-induced vitamin D deficiency. Given the nature of ketoconazole's action, simple oral vitamin D supplementation may not provide adequate protection, and calcitriol might need to be prescribed to avoid adverse effects of vitamin D deficiency. Monitoring is essential because the half-life of administered calcitriol tends to be prolonged in presence of ketoconazole.

Neomycin

Neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin); combination drugs: Adcortyl with Graneodin, Betnovate-N, Dermovate-NN, Gregoderm, Synalar N, Tri-Adcortyl, Trimovate.

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

It is widely accepted that extended use of neomycin can significantly decrease absorption or increase elimination of vitamin D as well as many other nutrients, including beta-carotene, folic acid, vitamin A, vitamin B_{12}, vitamin K, calcium, iron, magnesium, potassium, and sodium.[89]

Research

No specific evidence is cited because the literature treats this interaction as axiomatic.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing extended courses of neomycin are advised to coadminister a multivitamin and mineral supplement as a prudent measure to avoid potential drug-induced deficiencies. Separation of oral intake by at least 2 hours will reduce the risk of interreference with absorption of either preparation.

Orlistat

Orlistat (alli, Xenical).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Orlistat is a gastrointestinal lipase inhibitor that binds dietary fat and prevents its absorption. Such activity can interfere with the absorption of vitamin D and other fat-soluble nutrients and potentially induce deficiency patterns.

Research

In a 52-week, double-blind, randomized, parallel-group, placebo-controlled multicenter study, preceded by a 4-week, single-blind, placebo run-in period, James et al.[143] observed that vitamin D (and beta-carotene) concentrations decreased in patients treated with 120 mg orlistat three times daily, compared with those receiving placebo (even though fat-soluble vitamin levels remained within the normal range in the treatment group). Van Gaal et al.[144] conducted a 6-month, multicenter, randomized, double-blind, parallel-group clinical trial involving 676 obese men and women. Most subjects demonstrated reduced blood levels of vitamins D and A, but these remained within the clinical reference ranges, and only few individuals developed nutrient deficiency patterns that required supplementation. However, in a clinical trial involving 17 obese African-American and Caucasian adolescents receiving orlistat, 120 mg three times daily, McDuffie et al.[145] observed several significant nutrient depletion patterns despite coadministration of a daily multivitamin supplement containing vitamin A (5000 IU), vitamin D (400 IU), vitamin E (300 IU), and vitamin K (25 µg). In particular, mean serum levels of vitamin D were significantly reduced compared with baseline after 1 month of orlistat, despite multivitamin supplementation.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Predictably, in view of its known pharmacological effects, orlistat interferes with absorption of fat-soluble nutrients, including vitamin D. The question of whether, and for which individuals, the probable decline in vitamin D blood level reaches a threshold of clinical significance remains unclear and worthy of further clinical trials. Pending conclusive research findings, physicians prescribing orlistat for 6 months or longer are advised to err on the side of prudence and coadminister supplemental vitamin D (and possibly vitamin A), potentially in the form of a moderate-dosage multivitamin combination. Separating intake of orlistat and supplemental nutrients by 2 or more hours may reduce adverse effects on absorption. Notably, the U.S. Food and Drug Administration (FDA) requires that food products containing olestra, which also inhibits fat absorption, include vitamin D and other fat-soluble vitamins (i.e., vitamins A, E, and K).

Raloxifene

Raloxifene (Evista).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

The ability of raloxifene, a selective estrogen receptor modifier (SERM) that is an analog of tamoxifen, to inhibit bone resorption and maintain or increase BMD depends on calcium nutriture and vitamin D's role in enabling calcium absorption and bone metabolism. Vitamin D can increase effectiveness of the drug.

Research

Boivin et al.[146] found that the coadministration of calcium (500 mg) and vitamin D_3 (400-600 IU) with raloxifene increased the degree of mineralization of bone in postmenopausal women, as demonstrated by iliac crest biopsies. All currently approved bone-active pharmacological agents have been studied only in conjunction with supplemental calcium, and newer anabolic agents increase mineral demand in skeletal tissue and will thus require even higher levels of calcium repletion.[78]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Calcium and vitamin D are essential for maintaining bone mass and density and imperative to the success of drug therapies for inducing bone augmentation.[77] Deficiencies of both nutrients are common in the patient populations at highest risk for osteoporosis. The importance of exercise and sound nutrition (including adequate protein and phosphorus intake) as foundational cannot be overemphasized and is supported by growing evidence. Calcium has a clearly demonstrated effect of enhancing estrogen's effects on bone metabolism. Further, most research indicates that consistent exposure to sunlight provides a safe and effective, as well as otherwise beneficial, method of elevating vitamin D levels. Doses of 1500 mg calcium and 800 IU vitamin D daily provide prudent nutritional support for osteoporosis prevention and treatment.

Thus, a synergistic combination of oral calcium and vitamin D, within the context of an active lifestyle, constitutes the core proactive intervention within integrative therapeutics for all individuals at high risk for osteoporosis, or a foundational treatment for diagnosed bone loss. Notably, low serum vitamin D levels have been associated with the incidence of falls in older women,[85] and vitamin D has been found to be helpful in reducing the incidence of falls, a major factor in fracture risk, by improving muscle strength, walking distance, and functional ability.[86] Also, hormone supplementation or replacement regimens (conventional HRT, bio-identical estrogens/progesterone, herbal hormone precursors/modulators) should be considered if indicated in women.

In addition to these primary and secondary therapies, the use of raloxifene in postmenopausal women can provide a potent intervention in reversing bone loss and supporting healthy bone mass, although it does tend to increase, rather than decrease, menopausal symptoms. Raloxifene may also be useful in reducing the risk of breast cancer in this population.

Rifampin

Rifampin (Rifadin, Rifadin IV); combination drugs: isoniazid and rifampicin (Rifamate, Rimactane); isoniazid, pyrazinamide, and rifampicin (Rifater).

See also Isoniazid section.

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Coadministration Therapeutic, with Professional Management**

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Pharmacokinetic interaction occurs because rifampin is a potent inducer of hepatic drug metabolism, specifically (cytochrome P450) 2C9, 2C19, and 3A4. Rifampin inhibits CYP1A2 and increases oxidation of antipyrine and 6β-hydroxycortisol, potentially causing decreased plasma levels of 25-hydroxycholecalciferol (25-OHD), which represents the body stores of active vitamin D precursor.[147]

Research

In a small study with eight male subjects, Brodie et al.[147] found that a 2-week course of rifampicin (600 mg/day orally) produced a consistent fall in plasma 25-OHD levels of approximately 70%. Within the time frame of the study, plasma levels of 1,25-dihydroxycholecalciferol, PTH, and calcitonin were not significantly altered.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing rifampicin for extended periods would be prudent to coadminister supplemental vitamin D at a dosage level appropriate to the patient's age, weight, sun exposure, and other characteristics and needs. Regular monitoring of 25-OHD would be appropriate.

Thiazide Diuretics

Bendroflumethiazide (bendrofluazide; Naturetin); combination drug: bendrofluazide and propranolol (Inderex); benzthiazide (Exna), chlorothiazide (Diuril), chlorthalidone (Hygroton), cyclopenthiazide (Navidrex); combination drug: cyclopenthiazide and oxprenolol hydrochloride (Trasidrex); hydrochlorothiazide (Aquazide, Esidrix, Ezide, Hydrocot, HydroDiuril, Microzide, Oretic); combination drugs: hydrochlorothiazide and amiloride (Moduretic); hydrochlorothiazide and captopril (Acezide, Capto-Co, Captozide, Co-Zidocapt); hydrochlorothiazide and enalapril (Vaseretic); hydrochlorothiazide and lisinopril (Prinzide, Zestoretic); hydrochlorothiazide and losartan (Hyzaar); hydrochlorothiazide and metoprolol (Lopressor HCT); hydrochlorothiazide and spironolactone (Aldactazide); hydrochlorothiazide and triamterene (Dyazide, Maxzide), hydroflumethiazide (Diucardin), methyclothiazide (Enduron), metolazone (Zaroxolyn, Mykrox), polythiazide (Renese), quinethazone (Hydromox), trichlormethiazide (Naqua).

Interaction Type and Significance

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

Probability: **5. Improbable**

Evidence Base: □ **Inadequate**

Effect and Mechanism of Action

Thiazide diuretics induce changes in renal tubules that reduce calcium excretion and could potentially lead to hypercalcemia in rare instances and changes in vitamin D metabolism (particularly increases in serum levels of 24,25-dihydroxycholecalciferol).

Research

Riis and Christiansen[148] studied the actions of bendroflumethiazide (5 mg/day), along with 500 mg/day calcium, on vitamin D metabolism in a 12-month, placebo-controlled clinical trial in 19 healthy, early-postmenopausal women. Subjects in the thiazide group demonstrated a significant elevation in the serum concentration of 24,25-dihydroxycholecalciferol and a tendency toward decreased serum 1,25-dihydroxycholecalciferol, although mean serum 25-hydroxycholecalciferol remained unchanged.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Given the uncertain implications of such findings, physicians are advised to closely supervise and regularly monitor serum calcium levels when prescribing thiazide diuretics. Special testing before initiating or increasing any vitamin D supplementation is probably unnecessary.

Thioridazine

Thioridazine (Mellaril).

Interaction Type and Significance

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

Probability: **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Cholecalciferol (vitamin D_3), as a cytochrome P2D6 inhibitor, may decrease the metabolism of thioridazine via CYP isoenzymes.

Research

In a double-blind, randomized-order, crossover study of thioridazine pharmacodynamics, Hartigan-Go et al.[149] used debrisoquin, an agent presumed to be extensively metabolized by CYP2D6, to determine the hydroxylation status of thioridazine. They also found that thioridazine can prolong QTc intervals in a dose-dependent manner in normal subjects.[149] Furthermore, a manufacturer of thioridazine determined that the peak concentration (C_{max}) of thioridazine (single oral dose of 25 mg) is highly variable, and that some individuals are "slow hydroxylators" and others are "rapid hydroxylators." In regard to the effects of CYP2D6 inhibition, compared with placebo, thioridazine increased QTc intervals by 9 msec and 23 msec with 10-mg and 50-mg doses, respectively.[150]

Clinical Implications and Adaptations

Concomitant use of thioridazine and agents that inhibit CYP2D6 isoenzymes such as cholecalciferol is contraindicated and should be avoided. Evidence is lacking to suggest that supplementation with forms of vitamin D other than cholecalciferol (vitamin D_3) is problematic, and vitamin D support is often important in patients being treated with thioridazine.

Alternatives to thioridazine may need to be considered when supplementation with vitamin D_3 is critical to a patient's medical needs and central to the therapeutic strategy for their comprehensive care. Regardless, an alternate drug choice may

be necessary because this phenothiazine antipsychotic has been withdrawn from the market in many jurisdictions.

Verapamil and Related Calcium Channel Blockers

Evidence: Verapamil (Calan, Calan SR, Covera-HS, Isoptin, Isoptin SR, Verelan, Verelan PM).

Extrapolated, based on similar properties: Amlodipine (Norvasc); combination drug: amlodipine and benazepril (Lotrel); bepridil (Bapadin, Vascor); diltiazem (Cardizem, Cardizem CD, Cardizem SR, Cartia XT, Dilacor XR, Diltia XT, Tiamate, Tiazac), felodipine (Plendil); combination drugs: felodipine and enalapril (Lexxel); felodipine and ramipril (Triapin); gallopamil (D600), isradipine (DynaCirc, DynaCirc CR), lercanidipine (Zanidip), nicardipine (Cardene, Cardene I.V., Cardene SR), nifedipine (Adalat, Adalat CC, Nifedical XL, Procardia, Procardia XL); combination drug: nifedipine and atenolol (Beta-Adalat, Tenif); nimodipine (Nimotop), nisoldipine (Sular), nitrendipine (Cardif, Nitrepin), verapamil combination drug: Verapamil and trandolapril (Tarka).

Interaction Type and Significance

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

◇◇◇ **Impaired Drug Absorption and Bioavailability, Avoidance Recommended**

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

Probability: **5. Improbable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Verapamil is a calcium antagonist, whereas vitamin D facilitates calcium absorption and metabolism. An interaction involving supplemental vitamin D, due to pharmacodynamic antagonism, is theoretically plausible but considered improbable. Vitamin D (or calcium) supplementation could potentially interfere with the primary activity of verapamil, and thus its therapeutic effectiveness, by increasing calcium availability. Further, hypercalcemia induced by toxic levels of vitamin D may precipitate cardiac arrhythmia in patients taking verapamil, although this is extremely rare, if it ever occurs. Conversely, verapamil may decrease endogenous production of vitamin D. Verapamil may also induce target-organ parathyroid hormone (PTH) resistance.

Research

The evidence for this interaction is minimal, but it is often considered self-evident. In a 1982 in vitro study, Lerner and Gustafson[151] reported that verapamil inhibited 1α-hydroxyvitamin D_3–stimulated bone resorption in tissue culture. In an animal model using rats fed a high-calcium diet, Fox and Della-Santina[152] found that chronic oral verapamil administration decreased 1,25-dihydroxyvitamin D_3 [$1,25(OH)_2D_3$] levels (by reducing production) and increased plasma immunoreactive PTH (most likely by inducing target-organ PTH resistance). In contrast, verapamil produced no significant effect on $1,25(OH)_2D_3$ levels in rats fed a low-calcium diet.

Reports

Bar-Or and Gasiel[153] reported that calcium adipate and calciferol antagonized the heart rate–limiting effect of verapamil in a patient being treated for atrial fibrillation.

Clinical Implications and Adaptations

Physicians prescribing verapamil or other calcium channel blockers are advised to exercise caution regarding the concomitant use of vitamin D. This possible interaction can present strategic concerns because many patients receiving verapamil may also have or be at risk for osteoporosis, such that calcium and vitamin D support is an important concomitant need. For example, Holick[164] suggests that such patients typically need vitamin D support. Close supervision and regular monitoring, preferably within the context of integrative care involving health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics, are essential in cases where concurrent use of verapamil and vitamin D is clinically appropriate. In cases of overdose with verapamil or other calcium channel blockers, intravenous calcium chloride or gluconate is the treatment of choice.

Related Discussion

Calcitriol and Vitamin D Analogs

Alfacalcidol, calcitriol, dihydrotachysterol.

Investigations into the pharmacology and clinical application of $1,25(OH)_2D_3$, the hormonal active form of vitamin D, have proceeded far beyond those of the nutrient itself. In many situations, including adverse drug-induced effects on vitamin D metabolism, calcitriol has been administered to increase effective activated vitamin D levels. In some recent research and emerging clinical protocols, calcitriol has been used as a central component of the pharmacological repertoire, that is, as a drug and not as a nutrient.

Stio et al.[155] demonstrated synergistic immunoregulatory properties and inhibitory effect of cyclosporine A and vitamin D derivatives on T-lymphocyte proliferation in T lymphocytes prepared from ulcerative colitis patients. Such an alternative therapeutic approach in these patients could reduce the dose, and consequently the toxicity, of cyclosporine A. In an animal model using mice with breast tumor xenografts, Sundaram et al.[156] found that treatment with a vitamin D_3 analog, EB 1089, before ionizing radiation reduces tumor growth and induces apoptosis, without inducing hypercalcemia. In another in vitro experiment, Dunlap et al.[157] reported that treating human prostate cancer cells with calcitriol and its analog, 19-nor-$1\alpha,25(OH)_2D_2$, may potentiate the effects of ionizing radiation and make these cells more susceptible to the effects of radiotherapy.

In a phase II clinical trial, Beer et al.[158] demonstrated that coadministration of high-dose calcitriol to weekly treatment with the chemotherapy agent docetaxel (Taxotere) appears to improve the therapeutic response in men with hormone-refractory prostate cancer without compromising safety, with the combination providing as much as twice the efficacy as docetaxel alone, as measured by prostate-specific antigen (PSA) response rate. Subjects received oral calcitriol, 0.5 μg/kg, on the first day of the treatment cycle, followed by an infusion of docetaxel, 36 mg/m^2, on the following day. This sequence was repeated weekly for 6 weeks of an 8-week cycle until there was evidence of disease progression or unacceptable toxicity, or until the patient requested to be withdrawn from the study. The phase III, randomized clinical trials following from this study evaluate the use of weekly docetaxel versus weekly docetaxel plus calcitriol in hormone-refractory prostate cancer.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Antacids, Especially Magnesium-Containing Antacids

Aluminum carbonate gel (Basajel), aluminum hydroxide (Alternagel, Amphojel); combination drugs: aluminum hydroxide, magnesium carbonate, alginic acid, and sodium bicarbonate (Gaviscon Extra Strength Tablets, Gaviscon Regular Strength Liquid, Gaviscon Extra Strength Liquid); aluminum hydroxide and magnesium hydroxide (Advanced Formula Di-Gel Tablets, co-magaldrox, Di-Gel, Gelusil, Maalox, Maalox Plus, Mylanta, Wingel); aluminum hydroxide, magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); calcium carbonate (Titralac, Tums), magnesium hydroxide (Phillips' Milk of Magnesia MOM); combination drugs: magnesium hydroxide and calcium carbonate (Calcium Rich Rolaids); magnesium hydroxide, aluminum hydroxide, calcium carbonate, and simethicone (Tempo Tablets); magnesium trisilicate and aluminum hydroxide (Adcomag trisil, Foamicon); magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); combination drug: sodium bicarbonate, aspirin, and citric acid (Alka-Seltzer).

Chronic use of some antacids may alter availability, levels, and metabolism of vitamin D. Evidence is lacking to confirm this potential interaction or determine its patterns of clinical significance.

Calcitonin

Calcitonin

The effect of calcitonin (clinically used primarily for treatment of hypercalcemia, but also osteoporosis and painful bone metastases, especially of multiple myeloma) may be antagonized by supplemental vitamin D.

Digoxin

Digoxin (Digitek, Lanoxin, Lanoxicaps, purgoxin).

Vitamin D enhances calcium absorption and elevated calcium levels may potentiate the effects of digoxin and contribute to increased risk of digoxin toxicity, potentially precipitating cardiac arrhythmia. At toxic levels, vitamin D could aggravate hypercalcemia and increase adverse effects of digoxin. Conversely, digoxin can potentiate the arrhythmogenic effects of hypercalcemia, leading to a symptomatic rhythm disorder.[159]

Although pharmacologically plausible, evidence from clinical studies regarding a direct interaction between digoxin and supplemental vitamin D is lacking. The risks associated with elevated or unstable calcium levels in patients receiving digoxin therapy are well known.

Most cases of hypercalcemia are unrelated to vitamin D intake. Vitamin D toxicity from supplemental sources is uncommon, if not rare, and would usually require an extended period of excessive vitamin D intake. However, even though rare, hypercalcemia would be a characteristic of hypervitaminosis D and would carry a significant probability of clinical significance in an individual undergoing digoxin therapy.

The combined use of vitamin D and digoxin may be therapeutically appropriate but involves judicious prescribing, cautious scrutiny, and careful follow-up. In particular, close supervision and regular monitoring of calcium levels are appropriate and prudent when prescribing digoxin therapy, especially in conjunction with any agents that might alter calcium status. The probability of an adverse reaction is generally quite low, but the consequences of such an event could potentially be severe and rapid in onset once a critical mass (hypervitaminosis D, hypercalcemia) had been reached. Physicians and other health care practitioners are advised to discuss use of and create an inventory of herbs and nutritional supplements with their patients in a respectful yet frank dialogue. Vitamin D excess to the degree that could cause hypercalcemia through sun exposure is generally considered impossible.

Doxorubicin

Doxorubicin (Adriamycin, Rubex).

Supplemental vitamin D may enhance the effects of doxorubicin. Given the positive trend in the findings from studies investigating the coadministration of calcitriol with a range of conventional cancer therapies, this potential supportive interaction warrants clinical trials. In an in vitro experiment, Ravid et al.[160] found that $1,25(OH)_2D_3$ may enhance the susceptibility of breast cancer cells to doxorubicin-induced oxidative damage.

Flurbiprofen

Flurbiprofen (Ansaid).

Through its primary mechanism of prostaglandin synthetase inhibition or possibly through other activities, flurbiprofen appears to reduce calcium and vitamin D levels in individuals with hypercalcemia. Buck et al.[161] found that flurbiprofen reduced circulating $1,25(OH)_2D$ in patients with recurrent calcium lithiasis. In a double-blind study, Brown et al.[162] reported on an individual with sarcoidosis in whom flubiprofen reduced plasma calcium levels and urinary hydroxyproline excretion to normal, while plasma $1,25(OH)_2D_3$ remained high. Clinical trials are warranted to determine whether flurbiprofen might influence calcium and vitamin D levels in healthy subjects or individuals with conditions involving other calcium and vitamin D metabolic disorders.

Hydroxychloroquine

Hydroxychloroquine (Plaquenil).

In a case report, Barré et al.[163] stated that 24 weeks of treatment with hydroxychloroquine reversed hypercalcemia and returned calcium and $1,25(OH)_2D$ levels to normal in a 45-year-old woman with sarcoidosis undergoing hemodialysis. The authors noted that these findings demonstrated the capacity of hydroxychloroquine to inhibit the conversion of $25(OH)D$ to $1,25(OH)_2D$ and suggested "the efficacy of hydroxychloroquine as an alternate to corticosteroids in the treatment of hypercalcemia of granulomatous disease." Controlled clinical trials are warranted to follow up on this report and also to determine whether hydroxychloroquine might beneficially influence calcium and vitamin D levels in healthy subjects or individuals with conditions other than sarcoidosis. Pending clarification by such research, physicians prescribing hydroxychloroquine are advised to discuss the potential effects of calcium and vitamin D supplementation with patients and closely supervise and regularly monitor calcium and vitamin D status in individuals for whom such supplementation may be appropriate for comorbid conditions.

Indapamide

Indapamide (Lozol).

Indapamide is a thiazide-like diuretic, but evidence is lacking as to whether it might enhance the activity of vitamin D in the manner of thiazide diuretics and whether such interaction might rise to the level of clinical significance. Pending clarification by controlled clinical trials, physicians prescribing indapamide are advised to discuss the potential effects of vitamin D supplementation with patients and closely supervise and

regularly monitor calcium and vitamin D status in individuals for whom such supplementation may be appropriate for comorbid conditions.

Mineral Oil

Mineral Oil (Agoral, Kondremul Plain, Liquid Parafin, Milkinol, Neo-Cultol, Petrogalar Plain).

Mineral oil, as a lipid solvent, interferes with normal absorption of vitamin D (and other nutrients) and increases its elimination from the body. Some disagreement surrounds the degree of clinical significance, particularly with regard to vitamin D in particular, but most research has found that mineral oil interferes with the absorption of many nutrients, including beta-carotene, calcium, phosphorus, potassium, and vitamins A, D, K, and E. Chronic use of mineral oil can cause a deficiency of vitamins A, D, E, and K.[164]

If mineral oil is used for any extended period, concomitant administration of a multivitamin and mineral supplement would be generally be advisable. Malabsorption of fat-soluble vitamins due to ingestion of mineral oil can be minimized by administering mineral oil on an empty stomach or consuming vitamin or mineral supplements at least 2 hours before or after the mineral oil. In general, it is advisable to limit the internal use of mineral oil to less than 1 week.

Sodium Fluoride

Sodium Fluoride (Fluorigard, Fluorinse, Fluoritab, Fluorodex, Flura-Drops, Flura-Tab, Karidium, Luride, Pediaflor, PreviDent).

In an in vitro experiment using serum-free cultures of human marrow, stromal osteoblast-like cells, Kassem et al.[165] found that $1,25(OH)_2D_3$ potentiated fluoride-enhanced type I collagen production in a dose-dependent way (as well as production of ALP and osteocalcin), compared with sodium fluoride alone, which did not increase type I collagen production. Controlled clinical trials would be necessary to determine if coadministration of $1,25(OH)_2$-cholecalciferol and sodium fluoride might promote beneficial collagen growth.

Sucralfate

Sucralfate (Carafate).

In a multiclinical and randomized study involving 100 patients with chronic gastric ulcer, Patty et al.[166] reported that sucralfate may reduce intestinal absorption of vitamin D. However, in a clinical trial of 30 patients with chronic renal failure on intermittent hemodialysis, Vucelic et al.[167] found that sucralfate intake was associated with slight increases in serum calcium levels. Physicians prescribing sucralfate are advised to discuss the possible implications of vitamin D (and calcium) supplementation with patients for whom such nutriture is important to strategic clinical goals and to monitor vitamin D and calcium levels regularly should supplementation be deemed appropriate.

Warfarin

Warfarin (Coumadin, Marevan, Warfilone).

Based on a single letter published in *JAMA* (1975), concern has been raised about a possible adverse interaction between vitamin D and anticoagulant medicines such as warfarin.[168] The potential for increased activity of anticoagulants due to vitamin D has not been confirmed by other case reports or any substantial clinical research. Physicians prescribing warfarin should be aware of rumors arising from recurring reference to this warning of theoretical risk of enhanced drug activity from vitamin D supplementation. Even though the occurrence of this interaction would seem to be widespread if it represented a significant risk, given the widespread use of vitamin D, health care professionals are advised to discuss this theoretical concern, and the lack of evidence supporting it, with patients before initiating supplementation with vitamin D in doses greater than 10 μg (400 IU) daily. Nevertheless, in conventional practice, vitamin D supplementation at usual dosages is not considered contraindicated during anticoagulant therapy. In general, because warfarin interacts with such a wide variety of substances, it is wise to monitor the prothrombin time (PT) twice weekly when new medications or nutrients that are to be administered for more than a few days are added to the patient's regimen. Only in recent years have the profound interactions between warfarin and acetaminophen and between warfarin and cranberry juice been identified. There are likely many such interactions that are yet unrecognized. Frequent monitoring of the PT/INR when diet, medication, or nutrient regimens are changed is the best protection against untoward clinical events occurring from such as-yet unrecognized interactions, especially those that may occur only in patients with certain genetic polymorphisms.

NUTRIENT-NUTRIENT INTERACTIONS

Boron

Boron appears to play a significant role in converting vitamin D from 25-OHD to its active form [$1,25(OH)_2D$], thus facilitating calcium absorption. This observation is clinically relevant because it supports the practice of using supplemental vitamin D_3 with boron, rather than calcitriol, thereby avoiding the high costs of calcitriol.

After examining animal nutrition models, Hunt[169] concluded that that dietary boron alleviates perturbations in mineral metabolism characteristic of vitamin D_3 deficiency. Hunt et al.[170] found that dietary boron modifies the effects of vitamin D_3 nutrition on indices of energy substrate utilization and mineral metabolism in the chick. For example, chicks fed a diet containing insufficient vitamin D for 26 days exhibited decreased food consumption and plasma calcium concentrations, as well as increased plasma concentrations of glucose, β-hydroxybutyrate, triglycerides, triiodothyronine (T_3), cholesterol, and alkaline phosphatase (ALP) activity. After administration of boron, plasma glucose and triglycerides returned to concentrations exhibited by chicks that had been fed a diet adequate in vitamin D. Such findings support the coadministration of boron and vitamin D_3 as a potentially useful strategy in diabetes management. Likewise, boron elevated the numbers of osteoclasts and alleviated malformation of the marrow sprouts of the proximal tibial epiphysial plate in rachitic (vitamin D–deficient) chicks, thus correcting a distortion characteristic of vitamin D_3 deficiency.[171] In an experiment investigating the effects of dietary boron in rats fed a vitamin D–deficient diet, Dupre et al.[172] observed that introduction of boron into the diet resulted in higher apparent-balance values of calcium, magnesium, and phosphorus.

In a study involving male subjects over 45 years of age and postmenopausal women fed a low-magnesium and low-copper diet, Nielsen et al.[173] showed that administration of 3.25 mg of boron daily increased levels of plasma vitamin D_3.

Caffeine

Rapuri et al.[174] found that elderly women with high caffeine intakes had significantly higher rates of bone loss at the spine than those with low intakes, and that caffeine intake interacts

with vitamin D receptor (VDR) genotypes. Nevertheless, the role of caffeine as a risk factor for bone loss remains controversial.

Calcium

Coadministration of vitamin D and calcium, along with weight-bearing exercise and sunlight exposure, are generally considered the foundational approaches to calcium nourishment, attainment, and maintenance of bone mineral density (BMD) and prevention of bone loss.[175-177] A normal physiological function of vitamin D is to facilitate intestinal calcium absorption.

Although findings have varied, often significantly influenced by methodology (especially in meta-analyses), most research indicates that concomitant intake of vitamin D and calcium reduces risk of fractures and enhances bone health, particularly for individuals with a preexisting insufficiency and with consistent patient compliance. In general, according to Heaney and Weaver,[78] prudent nutritional support for osteoporosis prevention and treatment consists of 30 to 40 mmol calcium per day together with sufficient vitamin D to maintain serum 25(OH)D levels above 80 nmol/L (~25 µg or 1000 IU vitamin D daily).[78] In a Cochrane Library review of 38 randomized or quasirandomized trials, Avenell and Handoll[178] found that the risk of fractures of the hip and other nonspinal bones was reduced slightly in elderly people who are frail and at risk for bone fractures, particularly those who live in nursing homes or other institutions, if vitamin D and calcium were given. Nevertheless, the risk of spinal fractures did not appear to be reduced.

In a trial involving 944 healthy Icelandic adults, Steingrimsdottir et al.[41] found that with 25-OHD levels below 10 ng/mL (i.e., significant vitamin D deficiency), maintaining calcium intake above 800 mg/day appeared to normalize calcium metabolism, as determined by the PTH level, but in individuals with higher 25-OHD levels, no benefit was observed from calcium intake greater than 800 mg/day.

In 2005 and 2006, three major papers were published discussing the relationship between calcium, vitamin D, and osteoporotic fracture risk. Findings from the RECORD study (*The Lancet*, 2005) suggested a lack of benefit from concomitant calcium and vitamin D in the prevention of fractures in menopausal women.[39] Subsequently, Jackson et al.[42] (2006) used data from the Women's Health Initiative that questioned the assumption that calcium and vitamin D can prevent osteoporosis-related hip fractures. They randomly assigned 36,000 postmenopausal women to receive elemental calcium, as calcium carbonate (500 mg twice daily), plus vitamin D (200 IU twice daily) or a placebo for an average of 7 years. Notably, the average calcium consumption in both groups was approximately 1150 mg/day, close to the appropriate recommended intake level. After 7 years, subjects in the treatment group exhibited 12% fewer hip fractures than those in the placebo group, a finding that was not statistically significant. However, a deeper analysis of the data reveals that more significant differences appear when considering compliance and initial calcium intake levels. For example, on excluding women who were not adhering to the program, the reduction in fractures was greater, with 29% fewer fractures in the treatment group than in the placebo group, a statistically significant difference. Likewise, hip fracture risk decreased by about 22% in treated subjects whose initial calcium intake was low or moderate.[42] Overall, in both trials, compliance was only about 40% and 50%.

In contrast, Boonen et al.[179] conducted a multifaceted meta-analysis of major randomized, placebo-controlled trials that analyzed the effects of vitamin D alone or in combination with calcium. In one analysis they found that randomized clinical trials comparing vitamin D alone to placebo showed no effect. Likewise, a subsidiary analysis showed that low doses of vitamin D (< 800 units/day) exerted no effect. However, they demonstrated a statistically significant 21% reduction in risk of fracture, compared with placebo, among subjects receiving 800 IU vitamin D and more than 1000 mg calcium daily. The authors concluded that vitamin D exerts its beneficial effect on bone predominantly by increasing absorption of calcium.

In some individuals and with certain medical conditions, supplementation with vitamin D, particularly at excessive levels, can induce an excessive increase in the absorption of calcium and increase the risk of hypercalcemia and kidney stone formation.[42] The risk of such adverse effects may be influenced by the form of calcium used, as well as other, individual patient variables.

Phosphorus

Vitamin D may cause an increase in the absorption of phosphorus. The clinical implications of this potential pattern of interaction have yet to be fully investigated in controlled human trials.

Sodium

In a small clinical trial involving 11 normal subjects and two patients with postsurgical hypoparathyroidism, Breslau et al.[180] found that in normal subjects, sodium-induced renal hypercalciuria is accompanied by increased $1,25(OH)_2D$ synthesis and enhanced intestinal calcium absorption. Since this adaptive mechanism did not occur in two patients with hypoparathyroidism, the authors suggested that mediation of this effect by parathyroid hormone was possible.

Vitamin A

Vitamin A antagonizes some of the activity of vitamin D. High doses of vitamin A, given concurrently with vitamin D, tend to reduce the toxic effects of vitamin D.[181,182] Vitamin A toxicity, such as hepatotoxicity, must also be considered in such contexts.

The 182 citations for this monograph, as well as additional reference literature, are located under Vitamin D (Calciferol) on the CD at the back of the book.

Vitamin E

Nutrient Name: Vitamin E.
Synonyms: Vitamin E; d-alpha-tocopherol.
Related Compounds: d-beta-tocopherol, d-gamma-tocopherol, d-delta-tocopherol; tocopheryl acetate, tocopheryl succinate.
Trade Names: Aqua Gem E, Aquasol E, E-Gems, Key-E, Key-E Kaps.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Acetylsalicylic acid (ASA, aspirin) ⊕⊕/✗	Concomitant use of aspirin and vitamin E may provide an additive effect in reducing platelet aggregation and otherwise reducing cerebrovascular risk. Evidence mixed but suggesting positive trend for clinically significant supportive interaction; use of antioxidant could clarify findings and enhance preventive effect.	Coadminister aspirin with multiple antioxidants, including mixed tocopherols and coenzyme Q10.
Anthralin ☼	Combining topical application of vitamin E with anthralin can provide antioxidant protection against drug-induced lipid peroxidation and inflammation. Narrow but strong evidence indicating clinically significant supportive interaction.	Compound and coadminister.
Bile acid sequestrants ≈≈≈/◈	Bile acid sequestrants may interfere with absorption of vitamin E, as well as of folic acid and other fat-soluble nutrients. Despite mixed evidence, reasonable probability of clinically significant adverse effect on status of nutrients relevant to cardiovascular health, particularly in at-risk individuals.	Supplement with vitamin E and other affected nutrients away from medication.
Chemotherapy and radiotherapy ✗✗✗/⊕✗/◈≈≈/◈◈/⊕⊕/≈◈◈ Associated oral mucositis ☼	Vitamin E and other antioxidants may provide protective activity against lipid peroxidation and other damaging forms of oxidative stress induced by conventional oncological therapies and may exert synergistic therapeutic activity when coadministered in a systematic and clinically appropriate manner. However, inappropriate or ill-timed usage may interfere with therapies relying on action of free radicals for therapeutic effect. Evidence of interference is lacking while evidence of synergy is mixed. Research into strategic coadministration and clinical guidelines is preliminary and evolving. Blanket declarations of risk, efficacy, or clinical significance are premature and unsupported.	Avoid concomitant use outside appropriate care. Concurrent or alternating administration can be appropriate in certain clinical situations under close supervision and regular monitoring.
Cisplatin, oxaliplatin Platinum chemotherapy ☼/≈≈/⊕⊕	Coadministration of vitamin E may reduce the adverse effects of platinum-based chemotherapy due to free-radical damage, particularly neuropathies and nephrotoxicity, while compensating for nutrient depletion and potentially enhancing therapeutic efficacy. Growing body of evidence suggests a supportive interaction of clinical significance with appropriate clinical management.	Avoid concomitant use outside appropriate care. Concurrent or alternating administration can be appropriate in certain clinical situations under close supervision and regular monitoring.
Cyclosporine ⊕⊕/☼/✗	Vitamin E coadministration may reduce nephrotoxicity and other adverse effects of cyclosporine while enhancing its bioavailability and decreasing its clearance and steady-state volume of distribution.	Coadministration may be beneficial unless otherwise indicated. Supervise and monitor.
Dapsone ☼	The strong oxidative action of dapsone can cause hemolysis by damaging red cell membranes. Coadministration of vitamin E may partially protect against dapsone-induced hemolysis. Evidence supportive but mixed and inconclusive.	Coadminister vitamin E, preferably as mixed tocopherols; effect may be enhanced by other antioxidants.
Doxorubicin Anthracycline Chemotherapy ☼	Oxidative damage contributes to the cardiomyopathy typical of anthracycline chemotherapy. Vitamin E coadministration may mitigate such adverse effects through its antioxidant activity and enhance tolerance of adverse effects; synergistic effects also possible. Evidence of benefit inadequate; possibility of interference with drug activity contentious but unproven.	Coadministration of vitamin E, preferably as mixed tocopherols, may help prevent or treat cardiotoxicity. Consider coenzyme Q10 and other antioxidants, as well as l-carnitine, l-taurine, ginkgo, and fish oils. Concurrent or alternating administration can be appropriate in certain clinical situations under close supervision and regular monitoring.
Gemfibrozil ≈≈≈/◈≈≈	Gemfibrozil may reduce serum levels of alpha- and gamma-tocopherol, and other antioxidants. Evidence mixed and contradictory. Clinical significance uncertain.	Patients with or at risk for cardiovascular disease likely to benefit from a diet rich in vitamin E and other antioxidant nutrients; role of supplementation contentious.
Glyburide ⊕⊕	Vitamin E can reduce lipid peroxidation and may enhance glycemic control and improve insulin action. Evidence supportive but preliminary.	Diet rich in vitamin E and allied nutrients and emphasizing low glycemic index advisable. Supplementation, preferably as mixed tocopherols, may be appropriate. Regular monitoring of blood glucose levels essential.
Haloperidol ≈≈/☼/◈≈≈	Free radical production and oxidative damage caused by haloperidol contribute to tardive dyskinesia and other adverse effects, and	Coadminister vitamin E, preferably as mixed tocopherols; effect may be enhanced by other antioxidants. Supervise and monitor.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
	may be due, to some degree, to drug-induced vitamin E depletion. Research indicates that vitamin E coadministration may reduce adverse effects in certain patient subgroups with minimal risk of significant adverse effects or interference with drug activity.	
HMG-CoA reductase inhibitors (statins) ✗/◇≈≈/⊕⊕	Vitamin E may support therapeutic action of statin agents and reduce their adverse effects, particularly on oxidative status; however, vitamin E may interfere with therapeutic action of statins, but concerns remain unclear and unsubstantiated. Antioxidant combinations, including vitamin E, may interfere with the HDL-elevating activity of statin-niacin combinations, most likely through their interaction with niacin. Vitamin E may also enhance clearance of statins by promoting detoxification processes. Coadministration may enhance antihyperlipidemic therapy and reduce cardiovascular risk. Evidence is preliminary but emerging. Efficacy controversial and clinical significance unclear.	Statins (without niacin) may be compatible with administration of multiple antioxidant combinations emphasizing mixed tocopherols and coenzyme Q10. Supervise and monitor within an integrative strategy.
Omeprazole Proton pump inhibitors ⊕⊕⊕	Antioxidant activity of vitamin E may reduce esophagitis and support omeprazole therapy by increasing the mucosal resistance to oxidative damage from gastroesophageal reflux. Preliminary evidence indicates reasonable probability of clinically significant beneficial interaction from coadministration.	Coadminister. Drug dose may be reduced.
Orlistat ≈≈≈/○/◇	Orlistat may decrease absorption of vitamin E and other fat-soluble nutrients. Preliminary evidence indicates vitamin E depletion pattern with reasonable probability of clinical significance over extended period.	Supplement with vitamin E and other nutrients preventively or if indication of deficiency with extended orlistat therapy.
Warfarin Oral vitamin K antagonist anticoagulants ✗✗/⊕✗/⊕⊕	Research involving individuals not taking anticoagulants as well as warfarin-related case reports indicate that high-dose vitamin E may enhance effect of coumadin-derivative anticoagulants by decreasing vitamin K levels and activity, reflected by PIVKA-II, an undercarboxylated form of prothrombin produced in presence of vitamin K insufficiency. Further research is warranted to determine nutrient interaction between vitamins K and E in patients using oral anticoagulants and appropriate clinical responses to coadministration.	Closely monitor and titrate if coadministration is appropriate.

NUTRIENT DESCRIPTION

Chemistry and Forms

Alpha-tocopherol is either d-alpha (RRR) or dl- (all-racemic) alpha tocopherol.

Naturallly ocurring forms of vitamin E include tocopherols (d-alpha-tocopherol, d-beta-tocopherol, d-gamma-tocopherol, d-delta-tocopherol) and tocotrienols (alpha-tocotrienol, d-beta-tocotrienol, d-gamma-tocotrienol, d-delta-tocotrienol).

Physiology and Function

Vitamin E was discovered in the 1920s, but our comprehension of the full implications of this nutrient in health, dysfunction, and disease is only beginning to emerge. Alpha-tocopherol is the only recognized form of the lipid-soluble vitamin E in animal tissues and plasma. However, vitamin E antioxidants are a group of eight tocopherol and tocotrienol compounds, including four tocopherols and four additional tocotrienol (alpha, beta, gamma, delta), which occur naturally in foods. Research over the past decade has focused on this nutrient's role in antioxidant functions, but important discoveries have also emerged concerning the direct role of vitamin E in control of cell division, inflammatory processes, xenobiotic detoxification, blood cell regulation, and connective tissue growth.

Vitamin E absorption depends on the presence of bile and decreases as dosage increases. At normal levels of intake, about 50% of dietary vitamin E is absorbed. A diet high in unsaturated fat increases vitamin E requirements. Vitamin E is distributed to all body tissues but has a particular affinity for adipose tissue. Adipose tissue slowly accumulates vitamin E and then in time slowly releases it while the liver just briefly stores vitamin E, and does so continuously. *Alpha-tocopherol transfer protein* (TTP), present in the liver and cerebellum, is the lipophilic vitamin-binding protein responsible for the incorporation of alpha-tocopherol into lipoproteins and for the transport of alpha-tocopherol between membranes. Dietary intake of vitamin E is metabolized in the liver to CEHCs, which are then glucuronidated and excreted via the urine.

Vitamin E's principal physiological role is to act as an antioxidant to prevent free-radical damage (lipid peroxidation) and protect the stability and integrity of cellular tissues and membranes. Vitamin E's role in stabilizing cell membranes is especially important in the lungs and red blood cells (RBCs), which are particularly susceptible to oxidative damage because of their high oxygen tension. As a fat-soluble nutrient, this antioxidant activity occurs particularly in lipid media and protects fatty acids against oxidative damage caused by various pollutants, peroxides, and free radicals formed during metabolic processes. It also reduces formation of *lipofuscin*, an oxidized fat that has been implicated in the aging process. If insufficient vitamin E is present, polyunsaturated fatty acids (PUFAs) may become oxidized in the body, creating toxins that may lead to chromosomal damage and carcinogenesis. Alpha-tocopherol has been shown to inhibit platelet aggregation, enhance vasodilation, affect the expression and activity of immune and inflammatory cells, and inhibit the activity of protein kinase C, an important

cell-signaling molecule. Researchers have recently determined that vitamin E, especially as d-alpha-tocopherol, can act as a ligand for, and thereby increase the metabolic activity of, *pregnane X receptor* (PXR), which regulates a constellation of genes involved in detoxification of xenobiotics.[1] Vitamin E also plays an important role in preventing neurological abnormalities such as peripheral neuropathies.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Research into the role of vitamin E in health and disease has yet to mature and remains the subject of controversy and discovery. Within the conventional perspective on nutrition, the metabolic function of vitamin E is usually considered as still unidentified, although its major function as a nonspecific chain-breaking antioxidant is acknowledged and emphasized. In contrast, since the 1940s, health care professionals practicing nutritional therapeutics have often presented vitamin E as a primary component of health optimization, disease prevention, and therapeutic intervention. Although conventional medicine usually disclaims the value of antioxidant therapy via nutritional supplements in the primary prevention of cardiovascular disease and cancer, the lack of cohesive understanding of the role of vitamin E and other antioxidants in secondary prevention is also acknowledged. Clinical trials have typically investigated individual antioxidants, such as vitamin E, without considering that most health care professionals practicing nutritional therapeutics employ antioxidant formulations aimed at achieving synergistic action from multiple ingredients. Such factors may account for many of the recent inconsistencies and disappointments in outcomes of studies examining the efficacy of vitamin E supplementation for heart disease and other conditions. Further, research employing vitamin E, as with most other studies involving nutritional supplements, have often been designed without regard to the particular form of the nutrient(s) employed, dosage levels typical of informed clinical practice, or the underlying pathophysiological mechanisms.

This subject exemplifies the need for well-designed clinical trials focused on clearly defined health care goals and informed by an integrative approach utilizing the knowledge and experience of clinicians and researchers from a diverse range of perspectives. Furthermore, the conclusions of reviews and meta-analyses of vitamin E studies require a careful parsing of trial data based on form of the nutrient involved, design and time frame, concomitant therapies, and patient population characteristics if they are to be accurate and clinically useful. Fortunately, in the meantime, a broad consensus supports the primary value of a balanced and diverse diet rich in antioxidants as the foundation of health optimization and disease prevention.

Possible Uses

Acne, allergies, Alzheimer's disease, amyotrophic lateral sclerosis (risk reduction), anemia (sickle cell anemia and other types of hemolytic anemia), angina, anti-inflammatory, antioxidant, ataxia with isolated vitamin E deficiency (AVED), atherosclerosis, bronchitis, burns, cardiovascular effects, cataracts, cold sores, cystic fibrosis, dermatitis herpetiformis, diabetes mellitus, diabetic retinopathy (prevention), Down syndrome, Dupuytren's contracture, dysmenorrhea, epilepsy (pediatric), fibrocystic breast disease, fibromyalgia, hemolytic anemia (deficiency), hepatitis, herpetic lesions and postherpetic neuralgia, high-altitude exercise performance, human immunodeficiency virus and acquired immunodeficiency syndrome (HIV/AIDS) support, hypercholesterolemia, mild hypertension, hypoglycemia, immune support (especially for elderly), infertility, inflammatory thrombophlebitis, intermittent claudication, leukoplakia, lung cancer (risk reduction), macular degeneration, menopause (including hot flashes and atrophic vaginitis), menorrhagia (heavy menstruation), muscular dystrophy, myocardial infarction, nocturnal cramping, Osgood-Schlatter disease, osteoarthritis, pancreatic insufficiency, peripheral neuropathy (due to deficiency), photosensitivity, preeclampsia (risk reduction), premature infants, premenstrual syndrome, prostate cancer (risk reduction), psoriasis, Raynaud's syndrome, restless legs syndrome, retinopathy, retrolental fibroplasia, rheumatoid arthritis, scar tissue, seborrheic dermatitis, scleroderma, skin ulcers, spinocerebellar ataxia (due to deficiency), spontaneous abortion, sudden infant death syndrome (SIDS), sunburn, systemic lupus erythematosus (SLE), tardive dyskinesia, vaginal atrophy, vaginitis, wound healing, yellow nail syndrome.

Deficiency Symptoms

Frank vitamin E deficiency is rare in humans, but dietary intake in developed countries is often compromised by heavy reliance on processed foods. Very little vitamin E is transferred across the placenta, so premature infants, who are not breast-fed or supplemented, are susceptible to deficiency and subsequent damage of the retina (retrolental fibroplasia) if exposed to high oxygen tension from oxygen supplementation. Individuals with a genetic defect in alpha-tocopherol transfer protein (TTP) have an especially significant susceptibility to a severe vitamin E deficiency, characterized by low blood and tissue levels of vitamin E and progressive nerve abnormalities. Deficiency of vitamin E can cause a peripheral neuropathy, in which sensory neurons are particularly affected, such that the large-caliber axons die, ultimately resulting in a spinocerebellar ataxia.

Possible signs and symptoms of vitamin E deficiency include decreased integrity of RBC membranes, hemolytic anemia (with consequent elevated indirect bilirubin), peripheral neuropathy, spinocerebellar ataxia, elevated heavy metal levels, cataracts, cystic fibrosis, cholestatic liver disease, various lipid malabsorption syndromes, atrophy of reproductive organs, infertility, premenstrual syndrome, hot flashes, fibrocystic disease, benign prostatic hypertrophy, dry skin, eczema, psoriasis, poor wound healing, atrophy and weakness in skeletal and smooth muscles, and Osgood-Schlatter disease (also associated with selenium deficiency), as well as increased risk of cancer, atherosclerosis, rheumatoid arthritis, major depression, and preeclampsia. Sickle cell anemia and beta-thalassemia predispose to vitamin E insufficiency.

Dietary Sources

Unrefined, cold-pressed vegetable oils, particularly wheat germ oil, sunflower seed oil, and olive oil and all whole, raw, or sprouted seeds, nuts, and grains (especially whole wheat) are considered the best dietary sources of vitamin E. Asparagus, avocados, brussels sprouts, egg yolks, legumes, shrimp, spinach, sweet potatoes, and leafy green vegetables, generally, can be good sources. Although wheat germ can be an excellent source, it must be absolutely fresh (less than a week old) because the oil oxidizes rapidly, and rancid wheat germ does not contain active vitamin E.

Food sources can provide the recommended dietary allowance (RDA) level of 15 mg alpha-tocopherol per day, an

appropriate intake for many conditions, while offering a rich diversity of gamma-tocopherol and other tocopherols. However, clinical research indicates that the maintenance dosage levels and especially the higher range of therapeutic dosage levels, typically hundreds of units per day, required for some conditions may be difficult to obtain through diet alone. This is particularly true for individuals who reduce their intake of dietary fats, because vitamin E tends be more abundant in diets richer in fats. Moreover, recent research on vitamin E bioavailability shows that absorption of vitamin E is higher if it is part of or closely associated with the digestion of a food that contains fat. For example, grain cereal fortified with vitamin E raised plasma levels of new vitamin E more consistently and to higher levels proportionately than did vitamin E as a supplement only, with liquids on an empty stomach, or even taken with milk.[2] On a broader level, there is a growing body of evidence that large doses of vitamin E, especially if used without an accompanying diverse antioxidant network, may be deleterious for some individuals.

Tocopherols are oily yellow liquids that are water insoluble, heat and acid stable, and deteriorate with exposure to alkali, light, oxygen, iron, or lead. Frying of foods as well as freezing also decreases the potency of vitamin E. In contrast, tocopheryl esters, which are most often found in fortified foods (particularly breakfast cereals), tend to be fairly resistant to both frying and freezing (as well as highly bioavailable).

Nutrient Preparations Available

Although alpha-tocopherol has long been the standard of vitamin E supplementation, research is evolving to a greater understanding of the importance of naturally occurring forms and the advantages of mixed tocopherols. RRR-alpha-tocopherol, more commonly known as d-alpha-tocopherol, is the only form of alpha-tocopherol that occurs naturally in foods, whereas synthetic dl-alpha-tocopherol (all-racemic alpha-tocopherol) is composed of equal amounts of all stereoisomers. The establishment of d-alpha as the "active" isomer was based on the rat fetus resorption assay developed in the 1940s, in which only the d-alpha isomer is active; in pregnant rats made vitamin E deficient, the fetuses die and are resorbed, which is prevented only by d-alpha-tocopherol. The other isomers may have superior in vivo biological antioxidant activity, and gamma appears to have greater prostate cancer–preventive activity than alpha. The tocotrienols are much superior in cellular membrane protection because of a greater ability to move within membrane structures. Naturally occurring d-alpha-tocopherol is significantly more bioavailable, perhaps 200%, and exerts greater physiological activity than synthetic dl–alpha-tocopherol.[3] Some clinicians have reported that water-soluble forms of vitamin E can be better absorbed and more effective with individuals experiencing fat malabsorption problems, especially middle-age and menopausal women. Vitamin E is sold in both esterified and nonesterified forms but is usually manufactured as acetate or succinate esters because pure vitamin E compounds are easily oxidized. A tocopherol form is appropriate in topical use; tocopheryl forms require an enzyme to split the vitamin E from the acid moiety to which it is attached by an ester linkage.

Dosage Forms Available

Capsule, gel capsule; emulsified liquid drops, mycelized liquid drops; injection; liquid; ointment; powder; solution, oral drops; spray; suppository; tablet; topical.

Equivalencies:
1 mg d-alpha-tocopheryl acetate = 1.49 IU
1 IU all-racemic alpha-tocopherol = 0.45 mg

The current RDA is given in milligrams of alpha-tocopherol.

Dosage Range

Adult

Dietary: RDA based on RRR-alpha-tocopherol (d-alpha-tocopherol):

Adults, 19 years and older: 15 mg (22.5 IU)/day
Pregnancy (all ages): 15 mg (22.5 IU)/day
Breastfeeding (all ages): 19 mg (28.5 IU)/day

Supplemental/Maintenance: 15 mg/day, higher doses may not be more efficacious.[4,5]
Pharmacologic/Therapeutic: 400 to 2500 IU/day (excluding pregnant or lactating women) in clinical practice; 100 to 1000 IU/day in the scientific literature.
Toxic: The safe upper intake level (UL) of vitamin E for adults as d-alpha-tocopheryl acetate is 1500 IU/day (1000 mg), or 1100 IU/day dl-alpha.

Pediatric (<18 years)

Dietary: RDA based on RRR-alpha-tocopherol (d-alpha-tocopherol)

Infants, birth to 6 months: 4 mg (6 IU)/day
Infants, 7 to 12 months: 5 mg (7.5 IU)/day
Children, 1 to 3 years: 6 mg (9 IU)/day
Children, 4 to 8 years: 7 mg (10.5 IU)/day
Children, 9 to 13 years: 11 mg (16.5 IU)/day
Adolescents, 14 to 18 years: 15 mg (22.5 IU)/day

Supplemental/Maintenance: Not established.

Laboratory Values

Plasma vitamin E: Less than 11.6 µmol/L indicates deficiency.
Plasma alpha-tocopherol (µmol/L)/plasma cholesterol (mmol/L): Ratio less than 2.2 indicates deficiency. Accurate measurement of vitamin E status inherently includes the ratio of vitamin E/total cholesterol because vitamin E level in the blood is directly correlated with the blood lipid level.
Plasma tocopherol: Less than 10 µmol/L generally indicates deficiency.

Note: Alpha-tocopherol normally constitutes more than 90% of total plasma vitamin E.

There is no correlation between plasma levels and vitamin E stores. A serum peroxide value can give an indirect status.

SAFETY PROFILE

Overview

Vitamin E supplements are widely considered to be safe and unlikely to cause adverse side effects in most individuals at typical dosage levels. At common therapeutic doses intended for long-term use, 800 IU per day, vitamin E, in its various forms, is considered nontoxic in most individuals. Daily doses of 2000 to 3500 IU have been used in clinical setting for extended periods without adverse effects. Nevertheless, there

has been a recent trend in the scientific literature suggesting potential adverse effects of dosages significantly higher than the recently revised RDA. Warnings against use of dosage levels greater than 200 IU/day usually derive from trials using vitamin E as an isolated antioxidant, synthetic dl-alpha-tocopherol, and patients with pathologies, behaviors, diet, or other factors characterized by high oxidative stress. Meta-analyses and reviews encompassing such studies are limited by their failure to emphasize the clinical implications of such study factors and attendant mixing of findings from trials employing essentially different substances (e.g., natural vs. synthetic forms, multiple vs. single nutrient). Thus, a potentially dangerous pro-oxidant effect can be created when one or two antioxidants, especially in synthetic forms, are given in high dosages to individuals who are chronically antioxidant deficient and under increased oxidative stress. Even so, "higher circulating concentrations of alpha-tocopherol within the normal range are associated with significantly lower total and cause-specific mortality in older male smokers."[6] Unfortunately, the mainstream of scientific research and medical practice has yet to consider, let alone investigate this concept.

Nutrient Adverse Effects

General Adverse Effects

The rare occasions of adverse effects from supplemental forms of vitamin E, typically in high dosages for extended durations, have been characterized by fatigue, headache, hemorrhage, double vision, nausea, flatulence, diarrhea, gastrointestinal distress, and muscular weakness. One study, published in 2005 and widely publicized in the popular press when initially released online in late 2004, was a meta-analysis suggesting that high dosages of vitamin E were associated with a small increase in risk for all-cause mortality at doses above 400 IU daily among individuals being treated for various health conditions, and this dose-dependent increase began to be seen above doses of 150 IU/day. These researchers also found that the meta-analysis of the vitamin E studies involving low doses (i.e., < 200 IU/day) indicated a small decrease in all-cause mortality, although it did not reach statistical significance. These conclusions were based on meta-analysis from 19 randomized, placebo-controlled trials involving d-alpha-tocopherol and dl-alpha-tocopherol (synthetic form) in diverse populations, including high proportions of the elderly and high-risk individuals with chronic pathologies.[7] None of these studies included any of the other naturally occurring tocopherol or tocotrienol isomers of the vitamin E complex.

Pregnancy and Nursing

Note: With pregnant women, monitor plasma tocopherol concentrations (normal range, 6-14 µg/mL).

In one randomized, placebo-controlled trial involving 722 pregnant women at risk for preeclampsia, researchers observed a slightly elevated incidence of small-for-gestational-age neonates among women administered vitamin C (1000 mg) and vitamin E (RRR-alpha-tocopherol, 400 IU) versus placebo.[8]

Infants and Children

Reports of infant deaths from vasculocentric hepatotoxicity in 1983 due to parenteral administration of vitamin E were found to be related to the solubilizing agent polysorbate instead of vitamin E.[9] This compound, E-Ferol, was subsequently banned. In a 1989 review article, Mino[10] summarized a cautious perspective: "In the course of therapy with elevated dosages of vitamin E, administered either orally, intramuscularly, or intravenously, many problems arose in the infants, such as unexpected death, increased frequency of necrotizing enterocolitis (NEC) and sepsis, and the development of unusual symptoms including hepatic injuries."

Toxicity: Vitamin E toxicity is generally considered to be very rare. Increased risk of hemorrhage may result from vitamin E toxicity. A dose of 1800 IU/day has been shown to cause a prolonged bleeding time (an in vivo test of platelet function).

Contraindications

Chronic rheumatic heart disease: Avoid initial use of high doses; increase gradually.

Hypertension.

Congestive heart failure (CHF): Large doses of a single antioxidant supplement, such as vitamin E, in patients likely to be under oxidative stress who do not consume a diet rich in antioxidants, may contribute to further oxidative stress.

Precautions and Warnings

Hypersensitivity to vitamin E, source material, or any component of the formulation; intravenous (IV) route.

INTERACTIONS REVIEW

Strategic Considerations

Vitamin E deficiency resulting from inadequate dietary intake is relatively uncommon in the developed world, but it may occur within certain populations, such as elderly persons and institutionalized individuals. Further, a wide range of common drugs deplete key nutrients, including vitamin E and other antioxidants, and the risk of drug-induced deficiency of vitamin E and consequent adverse effects is considered to be substantial.

Conversely, supplementation with naturally occurring forms of vitamin E may prevent or reverse adverse effects of many medications. However, controversy continues as to whether coadministration of vitamin E with drugs that deplete it offers superior therapeutic outcomes, or whether such polypharmacy simply obscures the outcome or even interferes with intended drug actions.

The role of vitamin E in conventional medicine has undergone many sharp turns, particularly at the start of the twenty-first century, as a number of interventional clinical trials, as well as several meta-analysis studies, were published. Perhaps most importantly, the issue of single versus multiple isomers of vitamin E, as well as natural versus synthetic sources, reveals deep divisions within the medical and scientific community as to nutritional therapeutics and underlying assumptions. This pivotal factor in clinical practice, research design, and scientific discourse was further exacerbated by the recent redefinition of "vitamin E" away from the previous functional definition based on physiological action to a narrower, more pharmaceutic definition exclusively specifying d-alpha-tocopherol.

Any discussion of "vitamin E" first requires a common understanding of meaning and context and should begin with questions as to forms and sources being applied. Thus, studies referring to "vitamin E" could indicate alpha-tocopherol more exactly (although often failing to differentiate isomer and source), supplements containing multiple tocopherol isomers, supplements containing multiple forms of naturally occurring vitamin E (i.e., mixed tocopherols and tocotrienols), or food sources. Many controversies and much

confusion would be rapidly resolved if discourse was founded on such clear communication and consistent nomenclature. The clinical significance of such discriminations becomes apparent in the treatment of conditions such as congestive heart failure, in which the interaction between different forms of "vitamin E" may constitute one of the more significant physiological factors. The exclusive reliance on alpha-tocopherol in almost all clinical trials of vitamin E fails to acknowledge the inherent balance and synergistic interplay among alpha-, beta-, gamma-, and delta-tocopherol and thus limits both the immediate applicability of any resultant findings and their extrapolation.

Over the past 40 years the role of vitamin E in preventing heart disease has been the subject of often acrimonious debate and collegial miscommunication. The ongoing controversy regarding the role of vitamin E in the prevention and treatment of cardiovascular disease reveals a deep schism in the often opposing world views of the linear reductionistic philosophy that permeates much of conventional medicine, and the more holistic empirical approaches of "natural" medicine. This dynamic suggests an emerging paradigm that might offer novel approaches to research, prevention, and therapeutics that can transcend and yet be inclusive of previously conflicting viewpoints. *Oxidative stress* plays a central role in the physiopathology underlying many chronic degenerative diseases, particularly cardiovascular disease, but its clinical implications are not understood in a consistent and comprehensive way. The underlying assumption in the field was that if the antioxidant effect of vitamin E conclusively proved to be clinically significant, vitamin E would logically be confirmed as playing an integral role in the prevention and treatment of heart disease. The role of antioxidant nutrients has evolved through a cycle of ill-founded enthusiasm and premature expectations that verge on regarding them as a panacea, into a body of research using single antioxidants in high doses (and often synthetic forms), with mostly negative results, and toward an emerging reconceptualization of nutrients' physiological nature and function, clinical uses, and effects. The interactions between antioxidants and statin drugs provide an important illustration of this dialogue and suggest ways in which both research and clinical practice can mature.

Thus, over the past two decades, the attitude toward vitamin E has gone from acceptance and often enthusiasm in some quarters, especially in relation to heart disease, to near-condemnation in more recent papers. However, the limitations of the research thus far clearly point to the need for further research into the differences between pharmaceutical and food sources of vitamin E, the physiological functions of and interplay among the various forms of naturally occurring tocopherol isomers, and the implications of such findings in formulating preparations for research and clinical practice. Furthermore, the emerging knowledge of physiological detoxification systems, such as hepatic phase I, II, and III enzyme systems, and the operative mechanisms of nuclear receptors, such as pregnane X receptor (PXR), offers significant prospects for understanding the clinical significance of drug metabolism and its stimulation by vitamin E and other nutrients. Further research, education, and communication will also be necessary to clarify the importance of using naturally occurring forms of vitamin E, preferably mixed tocopherols and tocotrienols, within the context of a comprehensive antioxidant strategy and with a respect for the particular needs and vulnerabilities of specific patient populations.

Some aspects of this controversy may derive from differences in the research questions being asked, trial design, observational studies versus randomized controlled clinical trials versus meta-analyses, characteristics of subject populations, nutrient forms and dosages, dietary sources versus supplemental intake, concomitant dietary and lifestyle factors, polypharmacy, and outcome measures. From early research into the possible beneficial nature of the interaction between the two, the ground shifted dramatically to claims that antioxidants diminish the effectiveness of statins, and finally to frank warnings that key antioxidants such as beta-carotene and alpha-tocopherol might actually increase risk of coronary artery disease and heart failure.[11,12] Conversely, the unresolved concerns regarding the safety and ultimate efficacy of statin drugs increasingly suggest that the dominant paradigm of scientific knowledge of their nature and action (i.e., lowering of cholesterol) may provide an inadequate explanation of their preventive and therapeutic effects as observed in a wide range of conditions. Ultimately the key to resolving such apparent conflicts may reside in greater individualization of care, with reference to the emerging tools of pharmaco-/nutrigenomics, through titration of drug doses to effect and/or blood levels and close monitoring within a flexible, responsive, and evolving integrative approach.

Many of the issues that arise in clinical research regarding vitamin E reflect clinical experience with vitamin E in particular and nutritional therapies in general, and the role such interventions play in defining clinical options and shaping therapeutic strategy. For example, the HATS study published in fall 2001 (discussed later) was widely interpreted as a negative interaction between antioxidants and statins, but on closer analysis more likely shows a blunting effect of the antioxidants on the rise of high-density lipoprotein (HDL) cholesterol, more associated with niacin, rather than a direct effect on the statin therapy. Most statins have minimal if any positive effects on HDL, and often actually reduce HDL, along with low-density lipoprotein (LDL), which is why the statin-niacin combination has become widely used since that study. Even so, the accepted fact that simvastatin is metabolized by cytochrome P450 3A4 (CYP3A4) may be a potentially significant observation given the findings of a single in vitro experiment showing that alpha-tocopherol could theoretically stimulate drug metabolism, particularly through its effect on PXR, with subsequent increased expression of the CYP3A4 enzyme. Nevertheless, failure to include coenzyme Q10 and methyl donors in the nutrient mix may also have represented a significant limitation in the trial design. Such modification would have addressed underlying mechanisms at issue: the inhibitory activity of statins on endogenous synthesis of coenzyme Q10 and niacin's depletion of methyl donors, particularly in the liver. Correction of these two drug-nutrient interactions with supplementation might have led to a very different outcome.

Lastly, an important aspect of antioxidant function rarely factored into the design of clinical trials is a recognition of the pro-oxidant potential of antioxidants. One or two antioxidants, especially synthetic ones (e.g., all-*trans* beta carotene), given in high doses to individuals under high oxidative stress, who consume diets low in antioxidants (e.g., male Finnish smokers, alcohol/tobacco users), can create a situation in which the antioxidants are forced to act as pro-oxidants. The resultant deficit in the antioxidant network causes the carotene and/or tocopherol and/or ascorbate radicals to persist without being quenched, and thereby increase free-radical damage. The increased incidence of heart failure among high-risk individuals taking 400 mg/day of vitamin E (with ramipril), observed in the HOPE study, appears to reveal such an adverse effect of increased oxidative stress when a comprehensive antioxidant network is not available.[13] Subsequent meta-analyses will be limited by their

indiscriminate inclusion of trials using varied agents in isolation with diverse populations. Similarly, the related findings of HOPE and HOPE-TOO trials emphasized the limitations and potential adverse response to use of vitamin E as a single antioxidant in individuals characterized by a state of oxidative stress. These researchers reported that natural-source vitamin E (400 IU alpha-tocopherol daily) failed to significantly reduce risk of cancer or cardiovascular events, the primary focus of the study, and appeared to be associated with an increased risk of heart failure. It is noteworthy that the subject group comprised older patients (average age, >70 years) with a history of heart disease, stroke, or diabetes, most of whom demonstrated very strong risk factors and were taking numerous medications. Furthermore, the authors of this study, as well as most commentators, do not appear to have considered the established relationship between alpha-tocopherol and gamma-tocopherol and its implications in such a patient population. High doses of alpha-tocopherol are known to deplete gamma-tocopherol, not only disrupting the natural balance among the various forms, but particularly influencing the production of natriuretic hormone, which plays a central role in regulating fluid and salt balance and for which gamma-tocopherol is a precursor. Any gamma-tocopherol deficiency induced by alpha-tocopherol could further stress the heart in this already-compromised population and thus contributed to an increased risk of heart failure. The authors conceded that the "unexpected" results "cannot be confirmed at this time by other trials" and "could be due to chance."[11] Such findings reveal an emerging pattern, approaching consensus, confirming the lack of efficacy of an exclusively pharmacological approach to vitamin E therapeutics, narrowly defined as alpha-tocopherol, in achieving the successes attributed to "vitamin E," particularly in individuals with heart disease, diabetes, or similarly compromised conditions. The findings point strongly toward the appropriate use of nutrient-rich food sources, or at least their closest approximation in the form of supplements, providing coordinated, multiple antioxidants, particularly mixed tocopherols and tocotrienols (which are up to 50 times more potent antioxidants than the tocopherols).

As knowledge of interactive complexity at molecular and cellular levels unfolds, so do prospects for more appropriately designed clinical trials. The French SuViMax study, which coadministered five antioxidants, showed a cancer prevention effect in likely dietarily antioxidant-deficient males. This exemplifies the hypothesis that the larger the number of antioxidant nutrients combined, that act in both aqueous and lipidic compartments, the better the clinical results should be. As collective knowledge of the mechanisms and nuances of integrative therapeutics matures, so do prospects for increasingly relevant, large-scale, well-designed clinical trials focusing on clinical outcomes. In the meantime, the role of vitamin E as a key antioxidant is undergoing a reassessment as clinicians and researchers obtain greater knowledge and deeper insight into antioxidant networks, the influences of dietary and supplemental sources, and their roles in health promotion, disease prevention, and therapeutic intervention.

NUTRIENT-DRUG INTERACTIONS

Acetylsalicylic Acid (ASA, aspirin)

Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Given a perception of aspirin and vitamin E as both acting as blood thinners (e.g., reducing platelet aggregations), an additive effect from coadministration of these substances has been proposed.

Research

The emerging body of human research into the potential interaction between vitamin E and aspirin has yet to reach the plateau of evolution and clarity necessary to understanding the apparent inconsistencies between clinical practice and the scientific literature. Steiner et al.[14] conducted a double-blind, randomized clinical trial investigating the antiaggregating agent containing vitamin E in 100 patients at risk for transient ischemic attacks (TIAs). Over 2 years, subjects were administered either aspirin (325 mg) or aspirin plus vitamin E (400 IU/day). Comparing two randomized subgroups from both sets of subjects, those receiving the combination medication demonstrated a significant reduction in ischemic events and platelet adhesiveness. There was no significant difference in the incidence of hemorrhagic stroke, although both individuals who developed it were taking vitamin E. The authors noted that the coadministration of vitamin E and aspirin appears to be safe and concluded that "combination of vitamin E and a platelet antiaggregating agent (e.g., aspirin) significantly enhances the efficacy of the preventive treatment regimen in patients with transient ischemic attacks and other ischemic cerebrovascular problems."[14]

In a double-blind clinical trial into the related issue of vitamin E's impact in patients undergoing chronic warfarin therapy, Kim and White[15] found that none of the subjects who received vitamin E had a significant change in the international normalized ratio (INR). Looking at the controversial topic of antioxidant use by smokers, Liede et al.[16] performed an endpoint examination of a random sample of 409 male smokers, age 55 to 74 years, who had participated in a larger, controlled, double-blind clinical trial. They reported a statistically significant increase in gingival bleeding among subjects taking the combination of acetylsalicylic acid (ASA) and alpha-tocopherol (50 mg/day) compared with those taking aspirin alone (33.4% vs. 25.8%); ASA alone increased bleeding only slightly. These authors concluded that alpha-tocopherol supplementation, particularly when combined with aspirin, might

increase the risk of bleeding gums and other clinically important hemorrhage.

Subsequently, in an in vitro study, Celestini et al.[17] investigated the capacity of vitamin E to enhance the antiplatelet effect of aspirin by assessing the dose-response curves of platelet aggregation, dense body secretion, phospholipase C activation, and calcium mobilization in aspirin-treated platelets incubated with and without added vitamin E (50 and 100 mg daily). They also looked at the important issue of vitamin E's role in reducing platelet adhesion to collagen. These researchers demonstrated significant induction of maximal platelet aggregation and calcium mobilization compared with controls and concluded that vitamin E can potentiate the antiplatelet activity of aspirin by inhibiting the early events of platelet activation pathways induced by collagen.

The clear direction of this research, collectively, supports further research into the combined use of vitamin E, preferably naturally occurring tocopherols, together with aspirin, in the prevention of undesirable platelet aggregation, particularly thrombotic complications in atherosclerotic patients.[17]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

For decades, clinicians and patients have been exposed to research and subjected to debate on the potential benefits of both aspirin and vitamin E in the prevention of cardiovascular disease.[18-24] Unfortunately, the certainty of the evidence and its penetration into common knowledge have been delayed and obscured by the often contradictory and hyperbolic nature of the claims and counterclaims. At the time of this review, the evolving body of evidence suggests that the probable additive effect from coadministration of aspirin and vitamin E could enhance valuable antiplatelet activity or produce undesirable effects on hemorrhagic tendencies, depending on characteristics of the patient population, respective dosage and forms employed, and coordination of attending health care providers. Given the high likelihood that conscientious patients could be using both vitamin E and aspirin as daily preventive measures, it would seem critical that the nature and implications of this potentially beneficial interaction be clarified and guidelines for integrative practice management be developed and implemented. Innovative approaches, similar to the "polypill" proposed by Wald and Law,[25] incorporating tocopherols deserve further investigation as the clinical implications of vitamin E and antioxidants in relation to aspirin, statin therapy, and other conventional approaches reveal their nuances to well-designed clinical trials, especially if clinicians experienced in the dosage and forms of the nutrients involved are integrated into the research process. In particular, therapeutic use of both vitamin E and aspirin might benefit from a fresh view that expands beyond the long-held conception of their beneficial action deriving solely, or even primarily, from their effects on coagulability and opens into supportive and even nutritive effects. Through development of such integrative approaches to polypharmacy, especially toward preventive effects, clinicians of all therapeutic schools would do well to disown their historical prejudices for or against pharmaceuticals and natural products per se and focus instead on our shared avowed dedication to the health and well-being of those who entrust us with their care.

Pending further research, combined use of aspirin and vitamin E, particularly as d-alpha-tocopherol or other naturally-occurring forms, presents a potentially valuable asset in the emerging repertoire of pharmacological and behavioral tools for the prevention of excess coagulation and reduction of the incidence of hemorrhagic stroke, especially among individuals at increased at risk for TIAs. Nevertheless, there is a critical need to remain cognizant of the potentially dangerous increased tendency to bleed, which may represent a manifestation of vitamin E toxicity in some cases. Although individual needs must be assessed within the clinical context of each patient's genetic susceptibility, lifestyle risks, medical history, and other factors, 100 IU tocopherol, mixed or d-alpha, and 80 mg aspirin per day may provide a conservative starting point for such integrative care.

Anthralin

Anthralin (Anthra-Derm, Dithranol, Drithocreme, Micanol Cream).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:	Evidence Base:
2. Probable	◉ **Emerging**

Effect and Mechanism of Action

Anthralin causes skin inflammation as a result of free-radical formation, through lipid peroxidation and production of inflammatory endoperoxides or by a more direct mechanism.

Research

In a clinical trial, Finnen et al.[26] determined that topical application of the tocopherol form of vitamin E inhibited inflammation of forearm skin by scavenging free radicals of the oxygen species.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing anthralin as a topical antipsoriatic might reduce the risk of adverse effects by requesting that the pharmacist compound alpha-tocopherol into the preparation.

Bile Acid Sequestrants

Evidence: Cholestyramine (Locholest, Prevalite, Questran), colestipol (Colestid).
Extrapolated, based on similar properties: Colesevelam (Welchol).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:	Evidence Base:
2. Probable	▽ **Mixed**

Effect and Mechanism of Action

Through their intended effect of limiting absorption and assimilation of dietary lipids, bile acid sequestrants may prevent absorption of vitamin E, as well as of folic acid and other fat-soluble vitamins (A, D, K, carotenoids, and coenzyme Q10).[27-31]

Research

Researchers have investigated both supportive and depleting interactions between vitamin E and bile acid sequestrants, especially colestipol. Hodis et al.[32] found that the combination

of colestipol, vitamin E (100 IU/day) and niacin was associated with added benefits on progression of coronary atherosclerotic lesions, as demonstrated in serial coronary angiographic studies. Schwarz et al.[33] observed that during 24 months of colestipol therapy plus diet, serum vitamin A and E concentrations did decrease in the five patients with good drug adherence, but deemed the resultant concentrations as within normal limits and hence insignificant. In monitoring plasma levels of fat-soluble vitamins, including vitamin E, and several other nutrients in young patients with familial hypercholesterolemia after 5 years of colestipol therapy, Schlierf et al.[34] observed no adverse drug effects with respect to the previous parameters and noted that plasma levels of carotenoids and vitamin E were elevated in the patients according to elevated concentrations of lipoproteins. Tonstad et al.[35] conducted a study of 37 boys and 29 girls age 10 to 16 years with familial hypercholesterolemia, first in an 8-week, double blind, placebo-controlled protocol, then in open treatment for 44 to 52 weeks. They found that levels of serum folate, vitamin E, and carotenoids were reduced in the colestipol group.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although bile acid sequestrants inherently reduce absorption of fat-soluble nutrients such as vitamin E and alter their availability and functionality within the body, evidence is lacking as to whether and when this impingement on normal physiological processes results in clinically significant effects and deleterious outcomes. Depletion due to unintended effects on absorption of fat-soluble nutrients, including vitamin E, may not be adequate to adversely affect many segments of the population to a clinically significant degree, or at least one discernible using standard research methodology. Importantly, plasma levels of fat-soluble vitamins, especially vitamin E, are typically elevated along with the elevated concentrations of lipoproteins that are carriers of nutrients. Further, any such impact may be potentially problematic in susceptible individuals most at risk for deficiency patterns and increased risk of cardiovascular dysfunction and disease, especially through extended courses of treatment. If vitamin E is being taken as part of an explicit strategy to reduce oxidative stress, thereby possibly reducing risk of cardiovascular disease, and support healthy lipid metabolism, the potential interference from these agents needs to be considered in establishing dosage, timing, and form of any concomitant therapy using vitamin E. Water-soluble forms of d-alpha-tocopherol provides one readily available means of circumventing this potential adverse interference with normal assimilation of nutrients in individuals for whom vitamin E plays an essential role in clinical care strategy, whether for cardiovascular effects or other preventive or therapeutic effects. Otherwise, regular use of a high-potency multivitamin/mineral formulation will replace the nutrients depleted by the drug. Individuals taking vitamin E, or other nutritional supplements and some drugs, may reduce interference of absorption by cholestyramine, colestipol, or other bile acid sequestrants by allowing an interval of 1 hour before or 4 to 6 hours after the medication.

Chemotherapy (Various Agents)

Including cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox), docetaxel (Taxotere), doxorubicin (Adriamycin, Rubex), etoposide (Eposin, Etophos, VePesid, VP-16), fluorouracil (5-FU; Adrucil, Efudex, Efudix, Fluoroplex), gemcitabine (Gemzar), irinotecan (camptothecin-11, CPT-11; Campto, Camptosar), methotrexate (Folex, Maxtrex, Rheumatrex), mitomycin (Mutamycin), paclitaxel (Paxene, Taxol), vinblastine (AlkabanAQ, Velban, Velsar), vincristine (Leurocristine, Oncovin, VincasarPFS), vinorelbine (Navelbine).

Effect and Mechanism of Action

Oxygen radicals have increasingly come under investigation as highly toxic stressors contributing to the causes of many diseases, including many forms of cancer. Vitamins E, C, and A are well known antioxidant agents. *N*-acetylcysteine (NAC) is a free-radical scavenger and might access the endothelial cell, thus increasing intracellular glutathione (GSH) stores. Even so, some concerns have been raised that antioxidants might be contraindicated during chemotherapy because one way in which chemotherapeutic agents attack cancer cells is by causing oxidative damage.[36,37]

Research

A variety of test tube–based and animal studies have found vitamin A, C, and E to increase the effectiveness of chemotherapy in several types of cancer.[36,38-44] In a double-blind study, Wagdi et al.[45] found that an antioxidant combination consisting of vitamin C, vitamin E, and NAC provided protection against heart damage induced by chemotherapy without reducing its effectiveness. NAC therapy may be useful therapy in advanced cervical cancers, especially squamous cell carcinomas. Several researchers have offered the seemingly paradoxical conclusion that the appropriate administration of antioxidant inhibitors and/or free-radical–generating compounds may be a useful strategy in the treatment of solid tumors. After performing a comprehensive review of the relationship between chemotherapy and antioxidants, Weijl et al.[46] rebuffed warnings that antioxidants need to be avoided during chemotherapy, but also determined that definitive evidence was lacking to support the use of antioxidants to provide relief from the adverse side effects of chemotherapy. Subsequently, however, conference reports (unpublished proceedings) by Salignik and Zeisel at a 1999 American Society of Cell Biology meeting suggest that vitamin A–deficient and vitamin E–deficient mice were less susceptible to brain tumor progression than non–vitamin-deficient control animals. Salignik et al.[47] suggested suppression of free radicals by the antioxidant vitamins may suppress apoptosis (programmed cell death).

In a randomized, double-blind, placebo-controlled trial among 540 head and neck cancer patients treated with radiation therapy, Bairati et al.[48] found that coadministration of alpha-tocopherol (400 IU/day) and beta-carotene (30 mg/day) administered during radiation therapy and for 3 years thereafter resulted in "less severe acute adverse effects during radiation therapy" (vs. placebo), with that reduction being "statistically significant . . . for adverse effects to the larynx ... and overall at any site." However, "quality of life was not improved" by the nutrient coadministration. Moreover, the "rate of local recurrence of the head and neck tumor tended to be higher in the supplement arm of the trial." Notably, "beta-carotene was discontinued because of ethical concerns" during trial. The authors concluded that concomitant treatment "with high doses of alpha-tocopherol and beta-carotene during radiation therapy could reduce the severity of treatment adverse effects," but they cautioned that their data suggest that "use of high doses of antioxidants as adjuvant therapy might compromise radiation treatment efficacy."[48]

Kennedy et al.[49] conducted a 6-month observational study of 103 children with acute lymphoblastic leukemia (ALL) being treated with chemotherapy. They reported that a large percentage of children undergoing ALL treatment have inadequate intakes of antioxidants and vitamin A, and that lower intakes of antioxidants are associated with increases in the adverse side effects of chemotherapy. In particular, greater vitamin E intake at 3 months was associated with a lower incidence of infections.

Birdsall et al.[50] and Cancer Treatment Centers of America conducted an exploratory trial to investigate effect of concomitant naturopathic therapies on clinical tumor response to radiation for early-stage prostate cancer (tumor stages 1b through 2, N0,M0). External-beam radiation therapy of up to 72 Gy was given to 22 patients on a conventional 8-week treatment regimen, whereas the 13 patients in the naturopathic group received at least one antioxidant supplement, with the most frequent antioxidant naturopathic treatments including green tea extract, melatonin, and a high-potency multivitamin, vitamin C, or vitamin E. "All patients were monitored for at least 12 months (range 12-42) and no patient received concomitant hormonal therapy." The investigators reported that in the patients "who did not receive naturopathic [antioxidant] treatments, the median pretreatment PSA level was 5.4 ng/mL, the median PSA nadir was 0.66 ng/mL, and the median time to PSA nadir was 16.0 months," and in the "patients who did receive naturopathic treatments, the corresponding values were 5.8 ng/mL; 0.59 ng/mL; and 16.0 months." One tumor treatment failure occurred in the nonnaturopathic group "based on PSA elevation >2 ng from nadir which occurred at 14 months," but there were no treatment failures in the patients who received concomitant naturopathic regimens. The authors noted as "also significant that 9/9 patients in the non-CAM group were considered to be low risk (based on pretreatment PSA levels of 4-10 ng) whereas 3 patients in the CAM group were classified as intermediate risk (PSA > 10-20 ng) and 1 patient as high risk (PSA > 20 ng)" (PSA, prostate-specific antigen; CAM, complementary and alternative medicine). Thus, the authors concluded that "concomitant naturopathic treatment does not appear to inhibit the capacity of external beam radiation therapy to control localized prostate cancer, and does not interfere with either the magnitude of the response, the velocity of the response, or its durability for at least 1 year." They added that these "results provide definitive evidence that antioxidant-based CAM modalities, designed to improve patient tolerance, quality of life, and possibly improve survival, do not inhibit tumor responses that depend on oxidative [tumor] killing mechanisms elicited by external beam radiation therapy."[50] Although encouraging, this small, retrospective study did not have sufficient power to draw any statistically significant conclusions. Similar studies involving much larger groups of patients receiving radiotherapy are warranted.

Clinical Implications and Adaptations

Some oncologists have raised reasonable concerns that supplementation with antioxidants might interfere with or limit the effectiveness of chemotherapeutic agents and radiation therapy. However, no substantial prospective, randomized, controlled clinical research has emerged to support this speculation or to warrant considering antioxidants as contraindicated during chemotherapy or radiotherapy, and emerging evidence indicates that effects of coadministration (particularly during radiotherapy) are more likely to be beneficial or negligible than harmful.[50a] Many nutritionally oriented health care professionals consider the oxidative damage caused by chemotherapy to be a particularly troublesome adverse effect given that evidence increasingly points to oxidative damage as being a contributing factor in the causation of many cancers. Individuals receiving chemotherapy should consult their treating physician and a nutritionally trained health care professional about the potential value of adding antioxidants to their regimen before starting such concomitant use. Well-designed clinical trials addressing this issue are sorelyneeded, but are moving into the necessary state of refinement. Such trials are particularly difficult to perform because the potential antioxidant contribution from diet, and its extreme variability among cancer patients during treatment, can seriously confound the effects of adjunctive antioxidant intake. For studies to be meaningful, diet needs to be standardized, which is logistically difficult. Studies that use a small number of antioxidants (i.e, fewer than four agents) concurrently with high oxidative stress inducers, such as chemotherapy and radiation, in patients consuming an antioxidant-poor diet, also are likely seeing the oxidant effects of the "antioxidant" compounds, because the antioxidant network necessary to recycle oxidized antioxidants is severely compromised.

Oral Mucositis

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
2. Probable

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Acute reductions in plasma concentrations of essential nutrients, including alpha-tocopherol, have been associated with impaired immune responses in some clinical settings. In particular, oral mucositis, inflammation of mucous membranes, represents one of the most frequent complications during conventional cancer therapy using chemotherapy or radiotherapy. Topical vitamin E has been proposed as a preventive agent based on effects on inflammation and lipid peroxidation.

Research

In a randomized, double-blind, placebo-controlled study involving 18 patients, Wadleigh et al.[51] used topical vitamin E in the treatment of oral mucositis in patients receiving chemotherapy. They found that six of nine patients receiving vitamin E had complete resolution of their oral lesions, whereas lesions did not

resolve completely in eight of nine patients who received placebo. Lopez et al.[52] conducted further studies examining the efficacy of topical vitamin E for the treatment of this condition and found that although topical vitamin E applied once daily was beneficial to some subjects, others did not experience relief from their symptoms.

In 1998, Mills[53] demonstrated the beneficial modifying effect of beta-carotene on oral mucositis caused by radiation and chemotherapy. Subsequently, in a preliminary study, topical application of honey also proved to be of benefit against radiation-induced mucositis.[54] More recently, Ferreira et al.[55] conducted a randomized, placebo-controlled clinical trial involving 54 patients receiving radiotherapy as the only treatment for cancers of the mouth and oropharynx. Subjects were administered an oil solution containing 400 IU vitamin E twice daily or a placebo (presumed to be nonactive) containing 500 mg evening primrose oil twice daily, before every conventional fraction of 2 Gy (200 rad) and again 8 to 12 hours later during the 5 to 7 weeks of radiotherapy. Participants were instructed to dissolve each capsule and hold the oil in their mouth for 5 minute before swallowing. At the conclusion of the study, the occurrence of painful mucositis events was significantly less (21.6% vs. 33.5%) among subjects who had received vitamin E than those receiving placebo. Likewise, pain and eating restrictions were significantly less in participants receiving vitamin E compared with the placebo group. These findings demonstrate that vitamin E can be useful in preventing and reducing the severity of mucositis in patients receiving radiotherapy for head and neck cancer. The equivalent survival statistics between the two groups would argue against any interference by vitamin E's antioxidant activity with efficacy of the radiotherapy.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The research reviewed might be considered weak or unreliable because of its limited scale, but the collective conclusions indicate that topical vitamin E represents a potentially effective approach to the prevention of mouth sores typically associated with chemotherapy and radiation. The trend revealed in the extant research recommends that well-designed, placebo-controlled trials are warranted. In the meantime, conservative principles of care, with a preventive orientation and integrative repertoire, suggest that vitamin E may provide a safe and inexpensive remedy to a highly probable adverse effect. In such cases, topical application of alpha-tocopherol twice daily would be the form most likely to be effective; with alpha-tocopheryl being the less preferred form. Formulations combining vitamin E and selenomethionine might also be considered, especially as a radioprotective agent.

Cisplatin and Oxaliplatin

Cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ); oxaliplatin (Eloxatin).
See also previous section on mucositis.

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
2. Probable

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Cisplatin is one of the most active antineoplastic agents for the treatment of various malignant tumors. However, platinum-based chemotherapy regimens are often associated with a wide range of adverse effects and often irreversible damage, including nephrotoxicity, peripheral neuropathy, ototoxicity, gastrointestinal dysfunction, and myelosuppression. In particular, cisplatin therapy reduces antioxidant levels in the blood at the same time that it increases levels of free radicals and lipid peroxidation. Peripheral neuropathy is a particularly common adverse effect, especially affecting the hands and feet. Dorsal root ganglia are key sites in cisplatin-induced neurotoxicity because these are the neural tissue with the highest degree of platinum accumulation[56]; these ganglia also are the most vulnerable neural structures in vitamin E deficiency neuropathies.[57] Cisplatin neurotoxicity has been attributed to demyelinization of the sensitive axons of the peripheral nerve sheaths, gangliar cell loss of the dorsal root ganglion and neural body, and axonal degeneration of the posterior horns of the spinal cord, paralleling the neurotoxic damage induced by chronic alpha-tocopherol deficiency.[58] Oxaliplatin is a novel, third-generation, platinum-based anticancer agent, recently approved and now widely used to treat colorectal cancer, and it appears to be even more neurotoxic than cisplatin. Vitamin E supplementation apparently enhances antioxidant activity and prevents or limits free-radical damage.

Research

The neuropathy induced by cisplatin is characterized by symptoms of peripheral sensory neuropathy, with ataxia and areflexia, similar to that observed in alpha-tocopherol deficiency syndromes. McCarron et al.[59] observed that alpha-tocopherol deficiency determines a peripheral neuropathy and spinocerebellar ataxia caused by retrograde degeneration of the large-caliber axons in the peripheral nerves and degeneration of the posterior columns in the spinal cord.

Pathak et al.[60] reported potentiation of the effect of paclitaxel and carboplatin on a human lung squamous carcinoma cell line after pretreatment with an antioxidant mixture containing vitamin C, vitamin E, and beta-carotene.

A team of Italian researchers investigating the issue of cisplatin-induced neurotoxicity and potential benefits of vitamin E administration published two important papers in 2003. An animal study, with accompanying in vitro research, demonstrated that alpha-tocopherol supplementation provided for decreased severity of adverse effects, particularly protection from drug-induced lipid peroxidation and toxic sequelae, without compromising therapeutic effect, thus contributing to enhanced survival.[58] In their human trial, the team randomly assigned 27 individuals, age 28 to 74, with a wide range of cancers to receive cisplatin chemotherapy alone or cisplatin chemotherapy combined with alpha-tocopherol, 300 IU daily. Supplementation began 3 days before onset of cisplatin therapy and concluded after 3 months, with both objective and subjective assessments at the beginning, midpoint, and conclusion of the therapeutic trial. Subjects receiving both vitamin E and cisplatin reported significantly lower neurotoxicity scores at the conclusion of their treatment (2.1), compared with participants who been given cisplatin alone (4.7). Only 31% of the group receiving alpha-tocopherol developed nerve damage, whereas such adverse reactions occurred in more than 85% of those receiving cisplatin alone. The severity of nerve damage was significantly different, with only mild to moderate effects among the nutrient-supplemented group, whereas two members of the drug-only group experienced severe neuropathies.[61]

In a randomized, open-label, controlled trial, Argyriou et al.[62] investigated the effects of oral vitamin E (600 mg/day) on chemotherapy-induced peripheral neuropathy in 40 patients who underwent six courses of cumulative cisplatin, paclitaxel, or a combination regimen. Treatment was administered during chemotherapy and for 3 months after treatment cessation. Thirty-one patients completed the study; 4 of 16 patients in the vitamin E group demonstrated neurotoxicity versus 11 of 15 patients in the control group. One vitamin E patient and three controls experienced mild neurotoxicity. Moderate toxicity occurred in three vitamin E patients and five controls. Three controls developed severe neurotoxicity. The researchers concluded that the "relative risk (RR) of developing neurotoxicity was significantly higher in the control group than in the treatment group, RR = 0.34," and recommended a large, randomized placebo-controlled trial.[62]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The evolution of research into the interaction of vitamin E and cisplatin is clearly heading in a promising direction. Although the studies thus far are limited in scale and inherently preliminary in nature, they indicate that vitamin E coadministration, preferably with naturally occurring tocopherol(s), not only can compensate for nutrient depletion pattern and mitigate adverse drug effects, but also can offer the potential for employing higher concentrations of cisplatin, thus improving the antitumor agent's therapeutic index. Research with oxaliplatin may also reveal similar potential for coadministration. Strategic integrative protocols, adapted to the particular characteristics and needs of the individual patient, offer expanded possibilities for enhanced care and improved outcomes within the context of collaborative care involving health care professionals trained and experienced in both conventional oncology and nutritional therapeutics.

Cyclosporine

Cyclosporine (Ciclosporin, cyclosporin A, CsA; Neoral, Sandimmune, SangCya)

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability: **3. Possible**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

The use of cyclosporine as an immunosuppressive agent in the treatment of allograft patients presents with a significant incidence of adverse effects, particularly nephrotoxicity. The risk of such events is heightened because the drug is poorly bioavailable (~30%). Some individuals are unable to achieve or maintain therapeutic cyclosporine blood levels. Further, the antioxidant activity of vitamin E may provide protective support against the reactive oxygen species (ROS) induced by the drug's action and the lipid peroxidation products suspected in its toxic effects within the kidneys. Concomitant administration of vitamin E during cyclosporine therapy may enhance bioavailability and decrease clearance and steady-state volume of distribution of the drug, as well as reduce adverse effects and cost. Such a supportive interaction could potentially allow for decreased dosage levels of the medication. Vitamins E and C have also been used as adjunctive therapy in transplant patients on the basis that they might slow progression of transplant-associated arteriosclerosis.

Research

In a small study published in 1996, Chang et al.[63] investigated the effect of water-soluble vitamin E (d-alpha-tocopheryl polyethylene glycol 1000 succinate) on the oral pharmacokinetics of cyclosporine in 10 healthy volunteers. In those individuals who randomly received the vitamin E after two doses of cyclosporine (10 mg/kg orally), cyclosporine clearance and steady-state volume of distribution for the drug were significantly decreased, and an increased area under the curve (AUC) for cyclosporine was observed. In a human trial, using the same water-soluble vitamin E at 6.25 IU/kg twice daily, Pan et al.[64] determined that cyclosporine blood levels during the early posttransplant period were significantly improved in 26 liver transplant patients (both adults and children) previously unable to achieve or maintain therapeutic levels. In contrast, in a different application of cyclosporine, a subsequent in vitro study using a P-glycoprotein–expressing human lung cancer cell line suggested that alpha-tocopherol could antagonize the multidrug-resistance–reversal activity of cyclosporine A and other chemosensitizing agents.[65] Elsewhere, Parra Cid et al.[66] reported that antioxidant nutrients, including vitamin E, protect against cyclosporine A nephrotoxicity.

In a recent retrospective study of data on 22 consecutive heart transplant patients, reduced trough levels of cyclosporine were observed in those who took twice-daily doses of 400 IU vitamin E and 500 mg vitamin C, as compared to other patients. These researchers found no other interactions between the antioxidants and cyclosporine, but cyclosporine trough levels decreased from 136 to 103 ng/mL in the first 2 weeks after antioxidants were administered. The average decrease in trough concentrations was 25% but in some patients was as high as 60%. The authors concluded: "We also don't know what the mechanism of this interaction is, so that should be studied in a more detailed analysis."[67]

On a practical level, many substances interact with cyclosporine, and because of its erratic pharmacokinetics, drug levels are routinely used to determine doses. With such monitoring, any undesirable interaction effects can be readily corrected. Cyclosporine is a classic CYP3A4 intestinal enzyme substrate; some physicians routinely administer cyclosporine with grapefruit juice (which contains a CYP3A4 enzyme inhibitor) to reduce drug costs, since a smaller dose of the drug will produce a higher blood level due to a reduction in the first-pass drug metabolism by intestinal CYP3A4 enzyme. Vitamin E, or the combination of vitamins E and C, may have various effects on cyclosporine pharmacokinetics, but more research is needed to establish this.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Individuals undergoing immunosuppressive therapy with cyclosporine may benefit from concomitant administration of vitamin E, and possibly other antioxidants such as vitamin C. Such adjunctive therapy may reduce adverse effects and enable lower drug dosage levels while maintaining therapeutic efficacy. Effective care of these patients will require active collaboration among physicians trained and experienced in both conventional pharmacology and nutritional therapeutics within an integrative therapeutic strategy. Given that vitamin E and allied nutrients might alter cyclosporine absorption and pharmacokinetics and that a wide range in individual

responses has been reported, drug levels need to be checked regularly, perhaps more frequently than usual, starting at 2 weeks.

Dapsone

Dapsone (4,4' diaminadiphenyl-Sulphone)

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Dapsone is strongly oxidative in a way that damages the membranes of RBCs and can result in hemolysis.

Research

In several trials, individuals with leprosy or dermatitis herpetiformis taking dapsone were given 800 IU of vitamin E for periods ranging from 4 weeks to 3 months. Kelly et al.[68] found that dl-alpha-tocopherol acetate, 800 mg/day for up to 3 months, did not substantially ameliorate the hemolytic effect of dapsone at 100 mg/day. In another study of patients with dermatitis herpetiformis, vitamin E therapy was followed by vitamin C therapy, and then combined therapy with vitamins E and C. This study concluded that the vitamin C had exerted no beneficial effect, but that oral administration of 800 units of vitamin E daily for 4 weeks confers partial protective effect against dapsone-induced hemolysis in patients with dermatitis herpetiformis.[69] Subsequently, Lardo et al.[70] studied patients with leprosy and concluded that oral vitamin E, 800 IU/day, conferred partial protective effect but did not correct the hemolysis parameters produced by dapsone treatment, 100 mg/day, except for methemoglobin levels, which were a more sensitive indicator of the oxidant damage.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Preliminary clinical evidence suggests that vitamin E may counter the adverse effects of dapsone but remains somewhat inconclusive. However, supplementation of 800 IU daily could provide many other potential benefits for such individuals beyond the antioxidant effect against dapsone-induced hemolysis indicated in these studies. Furthermore, clinicians are advised to consider recommending a strict gluten-free diet for certain patients. Dermatitis herpetiformis is often secondary to an unrecognized gluten sensitivity (celiac sprue); such an approach over time may make dapsone treatment unnecessary in these cases.

Doxorubicin and Related Anthracycline Chemotherapy

Evidence: Doxorubicin (Adriamycin, Rubex).
Extrapolated, based on similar properties: Daunorubicin (Cerubidine), epirubicin (Ellence, Pharmorubicin), idarubicin (Idamycin, Zavedos), mitoxantrone (Novantrone, Onkotrone).
Similar properties but evidence lacking for extrapolation: Daunorubicin, liposomal (DaunoXome); doxorubicin, pegylated liposomal (Caelyx, Doxil, Myocet).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Doxorubicin is a highly effective antineoplastic agent, but cardiotoxicity, acute and chronic, is an adverse effect occurring in up to one third of the patients treated after a cumulative dose of 300 mg/m^2, and increasing sharply beyond a cumulative dose of 360 mg/m^2. Consequently, it is often used in less-than-optimal doses in an attempt to mitigate resultant irreversible and dose-dependent cardiomyopathy. As an antioxidant with a particular affinity for cardiac tissue, vitamin E has been investigated as a potential tool in mitigating such adverse effect and enabling treatment with higher dosage levels of doxorubicin.[71]

The cardiotoxicity of anthracycline chemotherapy agents can be of rapid onset and persist for decades, often absent cardiac complaints. The cardiotoxicity is multifactorial and involves oxidative stress, in part mediated by an iron-catalyzed Fenton reaction; iron-chelating agents have been shown to decrease doxorubicin cardiac toxicity. Two conditions of cardiotoxicity have been recognized. The first is a dose-independent idiosyncratic phenomenon appearing immediately after anthracycline administration and is based on a pericarditis-myocarditis syndrome in patients without previous cardiac disease. The second condition is dose related and characterized by progressive decline of left ventricular systolic function, as assessed by the ejection fraction on nuclear medicine and echocardiographic studies, which may lead to congestive heart failure (CHF). Diastolic dysfunction may also lead to CHF, with or without concomitant compromise of left ventricular ejection fraction. On pathological examination, progressive anthracycline-related cardiac damage may include restrictive endomyocardial disease, characterized by fibrous thickening of the endomyocardium, and dilated cardiomyopathy, as a result of myocardial fibrosis and hypertrophy of surviving myocytes. Symptoms can appear many years after completion of chemotherapy, although sequential assessment of left ventricular systolic and diastolic function will show compromise long before symptomatic CHF ensues. Risk of anthracycline-induced CHF is increased by radiotherapy fields that involve all or part of the heart.[72-74] In a longitudinal assessment of cardiac function in the 22 patients treated with anthracycline for osteogenic sarcoma or malignant fibrous histiocytoma, Brouwer et al.[75] found systolic dysfunction in more than a quarter of the patients and diastolic dysfunction in almost half after two decades (median, 22 years). Moreover, cardiac dysfunction was progressive, as measured at 9, 14, and 22 years.

Hair loss is another adverse effect typically associated with doxorubicin.

Cardiac Toxicity for Anthracycline Class of Antineoplastic Agents. Cardiac toxicity is similar between equipotent doses of doxorubicin and daunorubicin, slightly lower for epirubicin, and only one-sixth that of doxorubicin for equipotent doses of mitoxantrone. Doxil and DaunoXome (liposomal doxorubicin and daunorubicin, respectively) have negligible cardiotoxicity, presumably because of negligible cardiac exposure to the active drug with the pharmacokinetics of the liposome-encapsulated preparation.

Research

Initial studies using rodents found that vitamin E exerted a protective effect against doxorubicin-induced cardiotoxicity.[76,77] In 1979, Krivit[78] proposed that alpha-tocopherol might ameliorate or prevent cardiac dysfunction without impairing the drug's antitumor effectiveness. Subsequently, a study by Legha et al.[79] showed that use of the vitamin did not

compromise the drug's antitumor activity but also failed to demonstrate substantial protection against doxorubicin-induced cardiac toxicity.

Wood[80] reported the severity of hair loss typically associated with doxorubicin therapy might be ameliorated by administration of tocopherol at 1600 IU/day, a relatively high dosage. These findings were supported by a subsequent study using doxorubicin-treated rabbits that showed evidence of protection against doxorubicin-dependent inhibition of new hair growth after being fed a alpha-tocopherol–supplemented diet;[81] human trials have not been published confirming such potential efficacy.

Other investigations have focused on possible synergistic relationships between vitamin E and doxorubicin. In vitro research with human prostatic carcinoma cells by Ripoll et al.[82] found that vitamin E enhanced the medication's chemotherapeutic effects.

Review teams led by Weijl[46] and Quiles[71] noted that antioxidant activity can protect against chemotherapy-induced cellular oxidative damage and suggested that the body of evidence indicates that vitamin E coadministration might enable tolerance of higher doxorubicin dose levels, but concluded that evidence from human trials of the nutrient's ability to attenuate the drug's cardiotoxicity remained inadequate.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Pending further positive research findings, no substantive evidence exists to support the use of alpha-tocopherol as a method of reducing cardiac toxicity caused by doxorubicin. In the meantime, clinicians seeking to integrate such nutritional support into their treatment protocols might consider ubiquinone (coenzyme Q10, L-taurine, L-caritine, fish oils, and/or ginkgo), for which there is more substantial evidence of cardiac protection from doxorubicin.

Gemfibrozil

Gemfibrozil (Apo-Gemfibrozil, Lopid, Novo-Gemfibrozil).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

Probability: **4. Plausible**

Evidence Base: **▽ Mixed**

Effect and Mechanism of Action

Gemfibrozil may reduce serum antioxidant levels (coenzyme Q10, alpha-tocopherol, gamma-tocopherol) in a manner paralleling changes in lipid levels, but through mechanisms as yet unclear.[83]

Research

The evidence provides an incomplete understanding of the interaction between gemfibrozil and vitamin E. In a randomized, placebo-controlled, crossover trial of 21 men with combined hyperlipidemia, 10 to 12 weeks of gemfibrozil therapy reduced alpha- and gamma-tocopherol serum levels to the levels comparable to those of normolipemic control subjects.[83] Other researchers, also in 1998, reported an antioxidant activity attributable to gemfibrozil that resulted in significantly decreased LDL lipid peroxides and an increased LDL vitamin E/lipid peroxide ratio, with no observable effect on vitamin E status.[84]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The contradictory and incomplete evidence concerning the interaction(s) between gemfibrozil and vitamin E could be interpreted to suggest a depletion pattern. Clarification of this potential adverse interaction may require a larger study sample and a longer time. However, these seemingly contradictory findings may simply reflect individual pharmacogenomic variability and a normal physiological response to a reduction in serum cholesterol levels. Further, the context of the entire discussion is to some degree held in abeyance, pending further developments in the ongoing controversy regarding the respective roles of antihyperlipidemic drugs and antioxidants in promoting cardiovascular health and treating lipid disorders.

Glyburide

Glyburide (Glibenclamide; Diabeta, Glynase, Glynase Prestab, Micronase, Pres Tab).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability: **4. Plausible**

Evidence Base: **Preliminary**

Effect and Mechanism of Action

Glyburide is a sulfonylurea drug used in the treatment of type 2 (non-insulin-dependent) diabetes mellitus (NIDDM) and as such is designed to lower blood glucose levels. The nutritive status and physiological status of vitamin E have often been considered factors of potentially major significance in dysglycemia and development of type 2 diabetes mellitus. This long-standing hypothesis has grown more complex and subtle with the increased knowledge of the interplay between glycemic control and oxidative stress in health and disease. Thus, in addition to normalization of lipid peroxidation, vitamin E might stimulate pancreatic insulin-producing function. Both actions could improve blood glucose control in many individuals with type 2 diabetes and alter the appropriate dose levels of hypoglycemic medications. Notably, oxidative damage plays a central role in many of the pathological changes associated with diabetes, particularly peripheral neuropathies and diabetic retinopathy.

Research

Paolisso et al.[85,86] published two relevant papers in 1993. In a double-blind human trial with 10 healthy control subjects and 15 NIDDM subjects, they observed reduced oxidative stress and improved insulin action in response to 900 mg vitamin E per day for 4 months, compared to placebo.[85] After a randomized clinical trial with 25 type 2 diabetic subjects, they concluded that d-alpha-tocopherol (900 mg/day) for 3 months "seems to produce a minimal but significant improvement in metabolic control but not insulin secretion in elderly type 2 diabetic patients."[86] Subsequently, Balabolkin et al.[86a] prescribed vitamin E in daily doses 600 and 1200 mg to 41 type 2 diabetic patients, who were then divided into four treatment groups: "(1) diets, (2) predian, (3) glyburide, and (4) sugar-reducing drugs and insulin". The authors concluded that while receiving vitamin E, all groups demonstrated enhanced pancreatic insulin production and normalization of lipid peroxidation.[85] Sharma et al.[87] subsequently investigated the role of vitamin E in reducing levels of oxidative stress in

diabetic patients, in the uncontrolled diabetic state or under good glycemic control. They found that maintenance of glycemic control only partially reduced oxidative stress and that oxidant injury continued despite optimal control of the diabetes. After administering supplemental vitamin E for 4 weeks, they reevaluated these patients and observed a further reduction in the oxidative stress, suggesting that vitamin E supplementation might be helpful in reducing free-radical–induced oxidant injury in diabetic patients. These collective findings could be interpreted as supporting the hypothesis that vitamin E may promote blood glucose stabilization and prevent the oxidative damage typically resulting from dysglycemia and likely contributing to the cascading sequelae common among diabetic individuals.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Enhanced vitamin E intake, through dietary or supplemental sources, may modulate blood glucose levels and reduce oxidative stress resulting from dysglycemic states. Individual genetic susceptibility, diet, lifestyle and contextual stress (or supportive) factors, and pharmacogenomic variability in response to nutrients and medications all significantly influence vitamin E status and the impact of vitamin E supplementation in diabetic individuals taking glyburide or other oral sulfonylurea hypoglycemic agents. Individuals taking any medication for blood glucose and insulin control need to be especially attentive with self-monitoring whenever any of these variables is altered. In particular, changes that enhance glycemic control increase the risk of an unforeseen hypoglycemic reaction.

Haloperidol

Haloperidol (Haldol).

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

Probability: **4. Plausible**

Evidence Base: ▽ **Mixed**

Effect and Mechanism of Action

Haloperidol may deplete vitamin E levels and produce adverse effects similar to those of vitamin E deficiency and characteristic of conditions responsive to vitamin E therapy, particularly tardive dyskinesia. Treatment with conventional antipsychotic medications increases free-radical production and oxidative damage, which exerts neurotoxic effects and appears to contribute to the development of dyskinetic phenomena.

Research

Tardive dyskinesia is a common adverse effect of long-term therapy using haloperidol and related neuroleptic drugs and also occurs outside the context of drug reactions, for which some clinicians have found vitamin E to be an effective therapy. An animal study compared the effects of haloperidol on rats fed a normal or a vitamin E–deficient diet and found depleted vitamin E levels in the deprived group.[88] In 1993, Gattaz et al.[89] examined the issue of tardive dyskinesia as part of an investigation of vitamin E's ability to attenuate the development of haloperidol-induced dopaminergic hypersensitivity in rats. In a series of short-term, controlled trials, Adler et al.[90,91] investigated the therapeutic efficacy of alpha-tocopherol in the treatment of tardive dyskinesia, with generally positive findings, culminating in the 1998 publication of a 36-week study involving 40 subjects who received d-alpha vitamin E (1600 IU/day) or placebo, which confirmed and extended the earlier results.[92] However, shortly thereafter the same research group published a larger, prospective, randomized, nine-site trial of up to 2 years that showed no significant advantage from a similar treatment protocol.[93] A 1998 meta-analysis of studies focusing on vitamin E and tardive dyskinesia published since 1987 noted that the collective findings indicated that a significant subgroup (28.3%) of patients with neuroleptic-induced tardive dyskinesia who were treated with vitamin E showed a modest improvement, and that the supplementation was well tolerated, with only rare and clinically insignificant adverse effects.[94]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The role of increased oxidative damage in cases of tardive dyskinesia resulting from antipsychotic medications has become increasingly clear. However, as clinical studies have evolved, the weight of the evidence continues to shift away from exclusive use of tocopherol toward a greater appreciation of broader antioxidant approaches for prevention of neurotoxic effects and treatment of long-standing tardive dyskinesia.[95] The increasing use of atypical antipsychotics as effective treatments may also reduce the prevalence and incidence of drug-induced tardive dyskinesia. The emerging tools of pharmacogenomic assessment offer the potential for prescribing medications more precisely suited to a given patient, and thus less likely to produce adverse effects, and for sorting potential antioxidant nutrients or combinations to prevent oxidative damage and ameliorate drug-induced neurotoxicity. Pending further clinical trials with modified supportive protocols and drug-nutrient combinations, physicians prescribing haloperidol can present coadministration of vitamin E, preferably as naturally occurring tocopherols and possibly within a broader antioxidant formulation, as a potentially beneficial means of moderating adverse drug effects, with no known risk of interfering with the haloperidol's therapeutic action.

HMG-CoA Reductase Inhibitors (Statins)

Atorvastatin (Lipitor), fluvastatin (Lescol, Lescol XL), lovastatin (Altocor, Altoprev, Mevacor); combination drug: lovastatin and niacin (Advicor); pravastatin (Pravachol), rosuvastatin (Crestor), simvastatin (Zocor); combination drug: simvastatin and extended-release nicotinic acid (Niaspan).

Effect and Mechanism of Action

Vitamin E has long been presented as preventing the oxidative damage to LDL cholesterol that is generally considered a major

component of heart disease. Vitamin E appears to support the therapeutic action of 3-hydroxy-3-methylglutaryl–coenzyme A (HMG-CoA) reductase inhibitors (statins) and reduce their adverse effects, in the prevention and treatment of cardiovascular disease, particularly hyperlipidemia and atherosclerosis. In the critical area of endogenous antioxidant activity and inhibition of lipid peroxidation, statin drugs appear to exert an adverse impact on oxidative status, and statin therapy may enhance oxidizability of alpha-tocopherol and ubiquinol (coenzyme Q10). More recently, concerns have been raised that antioxidants, including vitamin E, may interfere with the HDL-elevating activity of statin-niacin combinations, even though statins alone generally lower HDL as well as LDL (with possible exception of atorvastatin). Vitamin E's specific role in such potential interference, including possible mechanisms of action, has not been presented in a precise and substantiated form. Nevertheless, simvastatin is metabolized by CYP3A4,[96] an important observation given the hypothesis that alpha-tocopherol may stimulate drug metabolism, particularly through its effect on PXR.[97]

Concomitant intake of vitamin E and other antioxidants with conventional lipid-lowering agents may improve some lipid parameters, particularly LDL cholesterol and triglycerides.[98]

Research

Over the past decade, emerging trends in both pathophysiologic and therapeutic research have expanded beyond the earlier emphasis on cholesterol to a deepening appreciation of the fundamental role of inflammation in cardiovascular risk and outcomes, as well as other disease processes.[99] Within this context, previous conceptions of both statin therapies and vitamin E, as an antioxidant and beyond, have yet to form a comprehensive model encompassing healthy function and prevention, therapeutics, and mechanisms of action.

The issue of cholesterol's contribution to heart disease, especially coronary artery disease (CAD), has often focused on the particular risks associated with oxidative damage to LDL cholesterol. Coronary endothelial function has been shown to improve under lipid-lowering and antioxidant therapy. Chen et al.[100] conducted initial research into the antiatherosclerotic effects of vitamin E, through preservation of endogenous antioxidant activity and inhibition of lipid peroxidation, when used with lovastatin and amlodipine (a calcium channel blocker). Palomaki et al.[101,102] showed that lovastatin treatment enhanced oxidizability of alpha-tocopherol and ubiquinol (coenzyme Q10). A subsequent randomized, double-masked, crossover clinical trial involving 28 men with coronary heart disease and hypercholesterolemia determined that alpha-tocopherol supplementation (450 IU daily) significantly increased the antioxidative capacity of LDL when measured ex vivo, which was partially abolished by concomitant lovastatin therapy.[103] In a small study of seven patients with hypercholesterolemia, Neunteufl et al.[104] found that coadministration of simvastatin (20 mg) and vitamin E (300 IU) improved markers of blood vessel elasticity, reduced total cholesterol and LDL cholesterol, and augmented alpha-tocopherol levels (normalized to LDL) more than simvastatin monotherapy.

Recent studies suggest that antioxidant nutrients, including vitamin E, may interfere with the therapeutic action of combination statin-niacin medications, which have become an innovative and increasingly respected form of statin therapy because of the synergistic interaction of the drug and vitamin. This combination has been shown to be effective in lowering LDL cholesterol and raising HDL cholesterol levels in high-risk individuals with hyperlipidemia, particularly in the context of personal history of cardiac events, malignant family history of heart disease, elevated inflammatory index markers (IIMs), or other high-risk factors.[105,106] As part of the HDL Atherosclerosis Treatment Study (HATS), researchers investigated the respective and collective roles of statins, niacin, and antioxidants (vitamins E and C, beta-carotene, selenium) in cardiovascular protection in patients with CAD and low HDL cholesterol. Cheung et al.[107] found that simvastatin-niacin substantially improved HDL parameters, but that these favorable responses were blunted by the antioxidants, especially with regard to Lp(A-I). In an accompanying paper, focusing on coronary atherosclerotic plaques and the occurrence of a first cardiovascular event, Brown et al.[108] found that the niacin-simvastatin combination was significantly superior to placebo with regard to average stenosis progression, but in participants also receiving antioxidants, this benefit was reduced to 0.7%, a finding interpreted as possible interference by antioxidants. When surrogate markers of cholesterol absorption and synthesis were later measured in a subset of HATS participants, at 24 months (on treatment) and at 38 months (off treatment), treatment with simvastatin-niacin continued to be associated with favorable changes in cholesterol metabolism and stenosis.[109] These findings were subsequently interpreted in many quarters as suggesting that adjuvant antioxidant administration was contraindicated in the treatment of hyperlipidemia and prevention of cardiovascular disease.[110,111]

A more critical analysis of the data suggests that the primary observed adverse interaction is between niacin and antioxidants, not statins and antioxidants. The HDL increases that occurred were probably attributable to the niacin therapy because low-dose simvastatin monotherapy has only limited effects in raising the levels of HDL cholesterol and apolipoprotein (apo) A-I. Thus, one or more of the antioxidants might be interfering with niacin's ability to alter the expression of proteins responsible for the formation of HDL. Further, the findings derived from the population studied may have limited general relevance to individuals who have only elevated LDL cholesterol levels (and normal HDL levels) and to women (who made up only 13% of the cohort). Also, with regard to HDL status, there was no detriment to the antioxidants alone (i.e., given to a group without simvastatin/niacin), and actually a slight benefit, which if involving thousands of patients as in the previous statin and thrombolytic trials, might have become a trend, or even statistically significant. Lastly, the composition of the antioxidant nutrient formulation used has been questioned. Given that niacin depletes the liver of methyl donors, thereby raising homocysteine levels and contributing significantly to the vitamin's hepatotoxicity, researchers might have obtained different results if they had included methyl donor–relevant nutrients with the antioxidants (e.g., folic acid, choline/betaine, and possibly coenzyme Q10, the synthesis of which is inhibited by statins). The principles of nutritional therapeutics also suggest that nutrient therapies might gain potency by looking beyond single-nutrient supplementation to multi-constituent formulations analogous to the antioxidant composition of fruits and vegetables, which involve complex mixtures of many antioxidant compounds rather than single entities.

Nevertheless, evidence from other quarters suggests that some forms of vitamin E may enhance clearance of statin drugs, as well as other hepatotoxic compounds. In particular,

alpha-tocopherol can stimulate the activity of pregnane X receptor (PXR), which regulates a constellation of genes involved in detoxification of xenobiotics and upregulates phase I, II, and III enzymes, especially CYP3A.[97] Given that simvastatin appears to be metabolized by CYP3A,[96] a valid case might be made that alpha-tocopherol, although not gamma-tocopherol,[1] may be facilitating liver clearance of the statin drug in a manner consistent with its protective function in xenobiotic detoxification. Significantly, especially when looking at integrative therapeutic options, fluvastatin and pravastatin are the two statins that are not metabolized by the cytochrome P450 3A4 system; they are also the two statins that have exhibited very low propensities to elicit myopathy when combined with other agents.[112] Apart from the necessary continuing research to confirm and elaborate these emerging findings, there remain unanswered fundamental strategic concerns arising from the adverse effects of any therapeutic agent(s) that obstruct and potentially damage normal liver function.

A broadening of the approach to prevention and therapeutics of CAD is coinciding with a growing understanding that the action of statins on cholesterol is not their exclusive or even primary therapeutic mechanism. The emerging emphasis on the role of inflammation in the pathogenesis of cardiovascular disease may provide a clearer understanding of the respective roles of both vitamin E and statins, as well as opening the discussion into further considerations of the potential therapeutic roles of natural thrombolytic agents, such as nattokinase and urokinase, proteolytic enzymes, and natural anti-inflammatory agents such as green tea, omega-3 fatty acids, garlic, and curcumin. The broad incidence and life-threatening implications of CAD and other forms of cardiovascular disease make further research into these complex questions imperative and indicate that building refinement and personalization into study design might open pathways to more definite conclusions and effective interventions better than would premature declarations and prohibitions.

In a related piece of innovative research, Hecht and Harman[113] used electron-beam tomography to assess the relationship of aggressiveness of lipid-lowering treatment to changes in calcified plaque burden in patients with subclinical atherosclerosis. They found that calcified coronary plaque progression appears to be unaffected by the degree of lipid lowering achieved by statin therapy. This study suggests that simply focusing on lowering LDL cholesterol levels may not produce the clinical outcomes presumed by manipulation of isolated pathophysiological phenomenon, as least with regard to slowing progression of subclinical disease in asymptomatic patients. Subsequently, Arad et al.[98] conducted a double-blind, placebo-controlled, randomized clinical trial investigating whether coadministration of conventional lipid-lowering therapy and antioxidants could retard the progression of coronary calcification and prevent atherosclerotic cardiovascular disease (ASCVD) events. They administered atorvastatin (20 mg daily), vitamin C (1 g daily), and vitamin E (alpha-tocopherol, 1000 U daily), versus matching placebos, to 1005 asymptomatic, apparently healthy men and women age 50 to 70 with coronary calcium scores at or above the 80th percentile for age and gender. Notably, all subjects received concomitant aspirin (81 mg daily). The authors halted the trial prematurely, after more than 4 years, because no statistically significant effect was observed on progression of coronary calcium score. They concluded that the combined treatment "induced substantial and sustained reductions in LDL cholesterol and triglycerides but failed to achieve conventional levels of statistical significance in the reduction of either all ASCVD events or CAD events, though statistically significant reduction of CAD events was found in analysis of the subgroup with a baseline calcium score of >400."[98] The lack of a group taking atorvastatin and aspirin with placebo antioxidant vitamins also makes the study uninterpretable in regard to the contribution, if any, of vitamins C and E.

Although these preliminary studies are important, the most definitive studies will be large, well-designed, randomized, double-blind trials of these therapies with clinical endpoints, such as cardiac events and survival, rather than the myriad of shorter-term surrogate endpoints, which have not been firmly established and universally accepted as "clinically relevant." Such studies are expensive, however, and tend not to involve natural products, which carry no patent protection and therefore (presumably) cannot subsequently be marketed profitably enough to recoup the considerable clinical research costs. Such studies will of necessity be funded by public institutions, which have the public health as their foremost concern.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Given the unresolved state of current knowledge, the collective evidence warns against overstated conclusions and generic clinical guidelines. Coadministration of vitamin E may reduce adverse effects and enhance efficacy of simple statin therapy (i.e., without niacin). However, the introduction of niacin into antihyperlipidemic therapy complicates the issue. In addition, individual variations in liver function and lipid metabolism, as well as pharmacogenomic variability in clinical response to conventional interventions, further confound any generic statin drug protocol that fails to account for each patient's characteristics and needs and a willingness to modify periodically the course of treatment in a flexible manner based on regular monitoring and patient preferences.

Integrative Medicine Approaches to Lipid Management. In clinical practice, it may be reasonable to add nutraceuticals to the standard diet and exercise phase of lipid management, then add a statin if the lipid profile is not brought into what is currently considered an acceptable risk profile. Likewise, future clinical trials investigating hypercholesterolemia and cardiovascular health might incorporate and extend the principle of reflecting healthy dietary intake by including not only the previously mentioned nutrients but also magnesium, vitamin B_6, copper, zinc, and chromium and liver-supporting agents such as silymarin, alpha-lipoic acid, L-carnitine, and flavonoids. For example, the emergence of policosanol also offers a potential natural alternative to statin therapy in some patients; it has been shown, in some but not all studies, to reduce serum cholesterol levels with a more favorable adverse effect profile than the statins. Furthermore, genetic factors influence individual variations in cardiovascular risk factors, lipid metabolism, and pharmacogenomic response to conventional antihyperlipidemic drugs. Thus, Zambon et al.[114] showed that in middle-aged men with established CAD and dyslipidemia, the hepatic lipase (HL) gene -514 C$\rightarrow$T polymorphism significantly predicts changes in coronary stenosis with lipid-lowering treatment that appear to involve an HL-associated effect on LDL metabolism. Subjects with the C:C genotype had the greatest decrease in HL activity and the most improvement in LDL density and HDL(2)-C with therapy, as well as the greatest angiographic improvement, compared with the other genotypes studied.

Omeprazole

Omeprazole (Losec, Prilosec).

Interaction Type and Significance

⊕⊕⊕ **Beneficial or Supportive Interaction, Not Requiring Professional Management**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Mucosal damage in erosive esophagitis is mediated primarily by free radicals. The antioxidant properties of vitamin E can increase the mucosal resistance in gastroesophageal reflux.

Research

Mirmomen et al.[115] conducted a preliminary double-blind, placebo-controlled clinical trial involving 58 individuals with moderate to severe erosive esophagitis; 29 received omeprazole 20 mg every other day plus vitamin E 800 mg daily, and 29 received omeprazole 20 mg every other day along with a daily placebo. At entry, all patients had been cured of endoscopically confirmed esophagitis by antisecretory therapy. All patients underwent endoscopic control to assess relapse rates at 24 and 48 weeks, or when they presented with symptoms. At 24 weeks, 82.8% of patients in the vitamin E group were still in remission compared with only 58.6% in the placebo group. Later, at 48 weeks, 79.3% and 55.2%, respectively, were in remission. Further, 68.9% of patients in the vitamin E group were symptom free versus 48.2% in the placebo group. The authors concluded that the combination of low-dose omeprazole and vitamin E is more effective than omeprazole alone for maintenance of moderate to severe esophagitis.[115]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The concomitant administration of omeprazole and vitamin E may provide an effective tool to physicians treating patients with recurrent esophagitis. In addition to expanding and extending proton pump inhibitor therapy by addressing underlying oxidative stress and inflammation and supporting restoration of healthy tissue and function, this integrative treatment option might also allow a lower dose of omeprazole. Further clinical trials involving a larger subject population are warranted.

Orlistat

Orlistat (alli, Xenical).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Orlistat inhibits gastric and pancreatic lipases in the lumen of the gastrointestinal (GI) tract to decrease systemic absorption of dietary fat, along with fat-soluble nutrients.

Research

Clinical trials and observational data indicate that orlistat may reduce absorption of vitamin E, and that in some individuals, this effect may be dramatic enough to result in deficiency symptoms.[116-118] In one trial involving 12 healthy volunteers who were administered a single oral dose of 400 IU vitamin E, pharmacokinetic assessment revealed that orlistat significantly reduced the absorption of vitamin E (~43% according to maximum concentration, and ~60% according to area under concentration-time curve), but not that of vitamin A. In a clinical trial involving 17 obese African-American and Caucasian adolescents receiving orlistat, 120 mg three times daily, McDuffie et al.[119] observed several significant nutrient depletion patterns despite coadministration of a daily multivitamin supplement containing vitamin A (5000 IU), vitamin D (400 IU), vitamin E (300 IU), and vitamin K (25 μg). In particular, during 3 to 6 months of orlistat treatment, acute absorption of alpha-tocopherol was significantly reduced compared with baseline levels ($p < 0.001$), but serum levels of alpha-tocopherol did not change significantly.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

A vitamin E supplementation strategy is advised in the event vitamin deficiency occurs in patients undergoing orlistat therapy.[120] More proactively, individuals taking orlistat for extended periods would benefit from prophylactic vitamin E supplementation,[118,121] 400 IU daily of naturally occurring tocopherols. Alternatively, employing a water-soluble form of the nutrient could bypass this interference, if nutritional treatment using vitamin E supplementation is part of a broader therapeutic strategy including orlistat.

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Primary: Warfarin (Coumadin, Marevan, Warfilone).
Extrapolated, based on similar properties: Nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar).

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

⊕✗ **Biomodal or Variable Interaction, with Professional Management**

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability: **4. Plausible**

Evidence Base: ▽ **Mixed** or ○ **Preliminary**

Effect and Mechanism of Action

Vitamin E may indirectly enhance the anticoagulant effect of warfarin by altering production of vitamin K–dependent coagulation factors, specifically at the vitamin K–dependent step of carboxylation at the gamma position of precursor prothrombin (factor II), as well as the other three vitamin K–dependent coagulation cascade enzymes, thus potentiating the warfarin-induced functional vitamin K insufficiency. Although no mechanism for vitamin E's action in these situations had been known until 2004, reductions in fully gamma-carboxylated vitamin K–dependent coagulation factors (II, VII, IX, and X) have previously been observed in subjects taking supplemental vitamin E.

Research

Corrigan and Ulfers[122] administered vitamin E (100 or 400 IU/day) orally for 4 weeks to 12 individuals receiving warfarin. The subjects showed no significant change in the prothrombin time (PT), factor II coagulant activity, or factor II antigen (which measures the amount of prothrombin present, but not its activity). However, a significant reduction was observed compared with pretreatment ratios on using a ratio of factor II activity to factor II antigen, as measured by the immunoreactive protein technique, suggesting that vitamin E influences the final activation step (gamma carboxylation) of prothrombin production, which is mediated by vitamin K. Further research by Corrigan[123] has supported the hypothesis that coagulation characteristics in normal individuals (i.e., those without vitamin K deficiency) are unaffected by vitamin E and that doses significantly higher than 400 IU/day are generally necessary to induce adverse effects in susceptible individuals.

In two independent, randomized clinical trials, Booth et al.[124] investigated the effect of 12 weeks of supplementation with RRR-alpha-tocopherol (1000 IU/day) on vitamin K status, as represented by several biochemical indicators, in 38 men and women with rheumatoid arthritis (study A) and in 32 healthy men (study B), none of whom were taking oral anticoagulants. Plasma phylloquinone (vitamin K_1) concentrations and the percentage of undercarboxylated osteocalcin (a marker of vitamin K insufficiency unrelated to coagulation proteins) did not change significantly in response to the vitamin E. However, the degree of mean PIVKA-II increased from 1.7 to 11.9 ng/mL in study A and from 1.8 to 5.3 ng/mL in study B after the 12 weeks of vitamin E supplementation, which represent highly significant increases. PIVKA-II is an abbreviation for the underactive form of prothrombin produced in the presence of either vitamin K deficiency due to dietary or endogenous production defects, or to the presence of a vitamin K antagonist such as Coumadin (warfarin). This significant increase in PIVKA-II, indicative of poor vitamin K status in adults not receiving oral anticoagulant therapy, strongly suggests that high doses of vitamin E may functionally antagonize vitamin K's activity in catalyzing gamma-carboxylation (activation) of at least factor II, and possibly also of factors VII, IX, and X. Insufficient levels of any one of these four vitamin K–dependent coagulation factors will prolong the PT/INR, although lowering of all four factors to a therapeutic level is necessary for full protection from inappropriate clot formation in the thrombophilic patient.

Reports

Cases of enhanced anticoagulant effect in response to high-dose vitamin E supplementation have been reported among patients taking oral anticoagulants. A single case report from 1974 led to a long-standing perception of risk from simultaneous use of warfarin and vitamin E and repeated warnings of contraindication. In this event, a vitamin K–deficient patient on warfarin therapy began to exhibit a range of adverse effects, including bleeding, ecchymoses, and prolonged PT, suggesting excessive anticoagulation within 2 months of beginning consumption of up to 1200 IU/day of vitamin E. Nevertheless, although decreased serum concentrations of blood-clotting factors were reported, warfarin serum concentrations were not altered, suggesting an enhancement of the warfarin effect on vitamin K–dependent coagulation factor synthesis. The patient's coagulation status normalized within 1 week of discontinuing the vitamin E supplementation.[125] Subsequently, Kim and White[15] investigated the pharmacological effect of concomitant warfarin and vitamin E in a randomized, double-blind clinical trial with 21 subjects receiving chronic warfarin therapy and found no significant changes in warfarin activity or INR in those who received vitamin E at doses up to 1200 IU/day. Within the context of integrative clinical management, the patient in the case report likely could have continued the vitamin E and reduced the dose of warfarin until the PT was again in the therapeutic range.

Clinical Implications and Adaptations

For many years, warnings have been voiced regarding potential adverse effects from use of vitamin E supplementation by individuals undergoing warfarin therapy, but only recently is the evidence beginning to suggest a possible basis for such contraindications. Continued research is warranted to determine whether the effects of this nutrient interaction are beneficial or adverse in and of themselves, whether they might be reversed by concomitant supplementation with vitamin K, and how they might affect oral anticoagulant therapy. Nevertheless, prudence supports operating under the assumption that the intended effect of warfarin therapy to cause functional vitamin K insufficiency, as reflected by a therapeutically prolonged PT and INR, may be enhanced by vitamin E coadministration, at least in some individuals undergoing long-term anticoagulant therapy. Furthermore, certain individuals with pharmacogenomic variations in vitamin K and warfarin metabolism, particularly in the context of vitamin K deficiency, may experience differing degrees of alteration in coagulation status in response to vitamin E supplementation. High doses of vitamin E for sustained periods may also mildly inhibit platelet activation. In the event of clinically significant changes in anticoagulant effects from concomitant use of warfarin and vitamin E, such effects would most likely be delayed in onset and of moderate severity. Physicians prescribing anticoagulant therapy are advised to monitor INR levels more frequently in patients who are beginning or increasing the dosage levels of vitamin E therapy, especially if those doses exceed 1000 IU/day, as well as in patients who significantly reduce their intake of vitamin E after sustained periods of supplementation.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Amiodarone

Amiodarone (Cordarone, Pacerone).

Research using human pulmonary artery endothelial cells, in vitro, suggests that alpha-tocopherol may reduce lung toxicity associated with amiodarone.[126] Establishing efficacy of and clinical protocols for this potentially protective interaction warrants further research.

Benzamycin and Benzoyl Peroxide

Benzamycin, benzoyl peroxide.

Benzoyl peroxide (BPO), one of the two components in Benzamycin (and also widely used in OTC acne preparations), is well known for promoting carcinogenesis in animals. An in vitro study, using a human keratinocyte cell line, found that human skin cells exposed to vitamin E were more resistant to cytotoxicity caused by BPO.[127] A subsequent human trial determined that alpha-tocotrienol supplementation significantly counteracted BPO-induced lipid peroxidation, although it did not significantly mitigate drug-induced barrier perturbation in the stratum corneum and increased transepidermal water loss.[128] Whether these medications cause similar adverse effects in humans, and whether any countervailing effect is

exerted by vitamin E, have yet to be researched in controlled human trials. Physicians prescribing such agents might suggest to their patients that supplemental vitamin E could potentially provide a means of reducing adverse effects associated with BPO and minimizing risk of further complications.

Cationic Amphiphilic Drugs

Chloroquine, Chlorpromazine, Desipramine, and Propranolol.

Cationic amphiphilic drugs (CADs) represent a wide range of therapeutic classes of medications used in the treatment of arrhythmias, depression, and seizure disorders and are well known for adverse effects on lysosomal phospholipid (PL) storage. Scuntaro et al.[129] conducted an in vitro study investigating the mechanisms of alpha-tocopherol action on drug kinetics and PL storage using a model of human cultured fibroblasts exposed to single and repetitive doses of desipramine and other CADs. They found that although alpha-tocopherol did not influence the initial, pH-dependent, rapid phase of drug uptake, it did inhibit, in a dose-dependent manner, the slow and cumulative phases of drug uptake and the accumulation of cellular phospholipids. The researchers hypothesized that this activity was caused by competition between alpha-tocopherol and CADs for PL complex formation and noted that the influence of alpha-tocopherol on drug uptake varies among different CADs. Although these findings suggest that alpha-tocopherol may counteract many adverse effects of CAD exposure on lysosomal PL storage and appear to restore normal membrane recycling, further research is necessary to determine if such benefits would be obtained in human subjects, and whether such activity would interfere with the effectiveness of the medications. Knowledge of the clinical implications of this apparent supportive interaction is too preliminary to suggest implementation in a clinical setting.

Clofibrate

Clofibrate (Aromid-S).

The issue of an interaction between vitamin E and clofibrate has been raised in two primary forms. A small, randomized, double-blind clinical trial investigated the effect of tocopherol on serum cholesterol and triglycerides in hyperlipidemic patients treated with diet and clofibrate and found no significant effect.[130] Others have voiced concern that clofibrate may impair absorption of vitamin E.[131] The severity of any resulting depletion, the frequency with which it occurs, and its clinical implications have yet to be determined in any conclusive form. However, because this is no longer a widely used lipid-lowering agent, further work in this area seems unlikely.

Cyclophosphamide

Cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox).

Oxidation in the liver is required for activation of cyclophosphamide. Vitamin E and other antioxidant nutrients could theoretically interfere with this process and reduce the agent's antitumor activity. However, separate animal studies have found that both vitamin A and vitamin C supplementation potentiated the antineoplastic activity of cyclophosphamide, particularly in the context of nutrient deficiency, without introducing any adverse effects.[38,132] In another animal study, combined cyclophosphamide treatment and vitamin E administration increased level of key enzymes (LDH, SGPT, SGOT, acid phosphatase, alkaline phosphatase) and produced greater efficacy in the treatment of fibrosarcoma in rats.[133] Furthermore, in a preliminary human trial, researchers reported increased survival among patients with small cell lung cancer (SCLC) whose treatment with cyclophosphamide and radiation was supplemented with a combination of beta-carotene, vitamin A, and vitamin E, compared with most published chemoradiation treatment regimens alone.[134] Because the current standard of care for SCLC involves platinum and etoposide with concurrent radiation treatment, however, it is difficult to extrapolate from the cyclophosphamide/radiation/vitamin E study. No research, human or otherwise, has been published investigating the occurrence or clinical implications of such a potential interaction specifically involving vitamin E. Well-designed clinical trials are warranted to determine the beneficial or detrimental nature of this potential interaction and to develop clinical protocols to optimize outcomes based on such emergent understanding. As noted previously, well-designed randomized clinical trials of cancer treatment, with and without antioxidant supplements, that carefully standardize the antioxidant contribution of diet are sorely needed.

Cytochrome P450 3A4 Substrates

Recent findings indicate that d-alpha-tocopherol interacts with the pregnane X receptor (PXR) and increases its activity.[135] PXR is a promiscuous nuclear receptor that is expressed in the liver and intestine and is activated by a broad array of endogenous and exogenous toxic compounds, especially lipophilic xenobiotics, including prescription drugs, herbs, pesticides, endocrine disruptors, and other environmental contaminants. On activation, PXR coordinately regulates a number of genes involved in drug clearance via the liver (cytochrome P450s) and intestine (P-glycoprotein) and thus upregulates phase I, II, and III enzymes.[136] This activity can provide a protective effect, especially in relation to xenobiotic clearance, but it also strongly suggests a potential for drug interactions, particularly involving medications metabolized by the CYP3A phase I enzymes. No work documenting actual drug interactions of clinical significance has been published at this time. However, more than 50% of the most frequently used prescription medications are metabolized by members of the CYP3A group.[97] Vitamin E acting as a PXR ligand could alter these PXR-mediated reactions. Unfortunately, the extent to which pharmacological doses of vitamin E modulate these pathways in vivo has not been determined. Although PXR regulation of hepatic alpha-tocopherol metabolism appears to be of central importance, other hepatic systems, such as P-glycoprotein (MDR2), participate in vitamin E trafficking and excretion.[1] If patients are taking vitamin E when they start a drug, and this drug is titrated to either effect (e.g., blood pressure) or blood level (e.g., cyclosporine), it most likely would be of no consequence, as long as they continued to take vitamin E. Starting or stopping vitamin E supplementation, however, while stable on a medication metabolized by those enzymes, could potentially be problematic, especially outside the context of professional supervision. Further research into this metabolic activity and related pharmacovigilance are warranted.

Fenofibrate

Fenofibrate (Lofibra, Tricor, Triglide).

In one controlled human trial, researchers found that the combination of 1000 IU d-alpha-tocopherol and 2 g ascorbic acid and prior to ultraviolet (UV) exposure dramatically blocked UV phototoxic lysis of erythrocytes associated with fenofibrate.[137] An animal study found that alpha-tocopherol content was decreased by 51% in the livers of fenofibrate-treated mice.[138] In another animal study, Chaput et al.[139] observed that coadministration of alpha-tocopherol and

fenofibrate produced a synergistic effect in which fenofibrate's lag phase was prolonged and its lipoprotein oxidation parameters were improved. Pending further controlled human trials, these preliminary findings suggest that coadministration of vitamin E, preferably as naturally occurring mixed tocopherols, might provide potential support to individuals undergoing fenofibrate therapy with minimal risk.

Gentamicin

Gentamicin (G-Mycin, Garamycin, Jenamicin).

Animal research indicates that alpha-tocopherol interferes with gentamicin-induced free-radical formation and suggests that this drug may be useful in preventing aminoglycoside oto-vestibulo-toxicity.[140] Vitamin B_{12} may provide a complementary protective effect.[141] Familial susceptibility to aminoglycoside ototoxicity has been discussed in several studies[142-144] and appears to be caused by the A1555G mutation in the mitochondrial DNA.[145]

Griseofulvin

Griseofulvin (Fulvicin, Grifulvin, Gris-PEG, Grisactin, Gristatin).

Research involving children and guinea pigs indicates that vitamin E coadministration can elevate blood levels of this antifungal medication and thus allow for reduced dosage levels of griseofulvin, well known for its adverse effects.[146,147] It appears that elevated alpha-tocopherol levels can reduce activity of the cytochrome P450 system enzymes that metabolize griseofulvin, thereby slowing the rate of griseofulvin biotransformation, which in turn allows for significantly sustained elevation of blood and skin concentrations of the medication. Even though these findings are still at a preliminary stage, physicians prescribing griseofulvin may want to discuss the option of concomitant vitamin E, 100 IU daily, with their patients as a safe and potentially effective means of reducing griseofulvin dosage levels and attendant adverse effects, without compromising efficacy. Conversely, the unsupervised concomitant use of griseofulvin and vitamin E, at significant dosages, could potentially increase severity of the drug's adverse effects due to CYP450 inhibition and subsequent elevation of blood and skin levels.

Hormone Replacement Therapy (HRT): Estrogen-Containing and Synthetic Estrogen and Progesterone Analog Medications

HRT, estrogens: Chlorotrianisene (Tace); conjugated equine estrogens (Premarin); conjugated synthetic estrogens (Cenestin); dienestrol (Ortho Dienestrol); esterified estrogens (Estratab, Menest, Neo-Estrone); estradiol, topical/transdermal/ring (Alora Transdermal, Climara Transdermal, Estrace, Estradot, Estring FemPatch, Vivelle-Dot, Vivelle Transdermal); estradiol cypionate (Dep-Gynogen, Depo-Estradiol, Depogen, Dura-Estrin, Estra-D, Estro-Cyp, Estroject-LA, Estronol-LA); estradiol hemihydrate (Estreva, Vagifem); estradiol valerate (Delestrogen, Estra-L 40, Gynogen L.A. 20, Progynova, Valergen 20); estrone (Aquest, Estragyn 5, Estro-A, Estrone '5', Kestrone-5); estropipate (Ogen, Ortho-Est); ethinyl estradiol (Estinyl, Gynodiol, Lynoral).

HRT, estrogen/progestin combinations: Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); conjugated equine estrogens and norgestrel (Prempak-C); estradiol and dydrogesterone (Femoston); estradiol and norethindrone, patch (CombiPatch); estradiol and norethindrone/norethisterone, oral (Activella, Climagest, Climesse, FemHRT, Trisequens); estradiol valerate and cyproterone acetate (Climens); estradiol valerate and norgestrel (Progyluton); estradiol and norgestimate (Ortho-Prefest).

Extrapolated, based on similar properties: HRT, estrogen/testosterone combinations: Esterified estrogens and methyltestosterone (Estratest, Estratest HS).

Over 6 months, Clemente et al.[148] treated 15 postmenopausal women with climacteric symptoms using 50 µg/24 hours estradiol transdermally applied twice a week for 21 days and a daily dose of 10 mg oral medroxyprogesterone acetate, which was added for 12 days in each treatment cycle. Their preliminary findings suggest that HRT can preserve the content of alpha-tocopherol and beta-carotene in LDL particles and keep the LDL in a reduced antioxidant state. In a randomized study involving 66 postmenopausal women, Inal et al.[149] found that concomitant administration of transdermal estradiol and vitamin E (600 mg/day, orally) improved LDL, HDL, and total cholesterol status, compared to pretreatment levels. However, within the Women's Angiographic Vitamin and Estrogen (WAVE) Trial, all-cause mortality increased in postmenopausal women, with at least one coronary stenosis at baseline coronary angiography, who were administered 400 IU vitamin E plus 500 mg vitamin C, both twice daily, eversus placebo.[150] These apparently contradictory findings strongly suggest further research into hormone metabolism and variable responses to exogenous administration of estrogen compounds, particularly in the presence of nutritional supplementation.

Women appear to clear CYP3A substrates more efficiently than men[151] and may possess additional alternative vitamin E–metabolizing systems, perhaps under the regulation of estrogen. Estrogen is metabolized by CYP3A4[152] (phase II), and some CYP3As may be regulated by estrogen. Alpha-tocopherol appears to induce the metabolic activity of PXR, a known regulator of steroid hormone and sterol homeostasis,[153] and thereby upregulate CYP3A4, resulting in stimulation of drug metabolism. Consequently, estrogen and alpha-tocopherol may interact through nuclear receptors, particularly nuclear estrogen receptor (ER) and PXR. The clinical implications of these potential interactions remain unclear, particularly given the evolving evidence concerning HRT's effect on cardiovascular risk and the emerging state of knowledge regarding estrogen conjugation and related detoxification systems.

Insulin

Animal-source insulin (Iletin); human analog insulin (Humanlog); human insulin (Humulin, Novolin, NovoRapid, Oralin).

Clinical experience and some human trials have suggested possible efficacy of vitamin E in improving glucose tolerance in individuals with diabetes. If such findings are confirmed by well-designed clinical trials, the central issue of an interaction between insulin and vitamin E must be the avoidance of hypoglycemic states. In such cases, clinical management within an integrative strategy characterized by collaboration among health care professionals experienced in conventional pharmacology and nutritional therapeutics becomes imperative. However, to further complicate the always-complex and individual issue of dysglycemia and physiological compensations, a trial by Skrha et al.[153a] reported that 3 months of vitamin E (600 mg daily) was associated with a deterioration in insulin action and fibrinolysis in obese type 2 diabetic patients. Such seemingly contradictory findings remind us that further research is necessary to establish a clear understanding of the complex interrelationships among insulin resistance, glucose

regulation, oxidative stress, and obesity. Pending such discoveries, caution is warranted regarding self-prescribing of high doses of supplemental vitamin E by diabetic individuals; conservative practice would especially caution against rapid escalation of dosage levels among obese diabetic patients. As with any introduction of changes intended to alter metabolism significantly and affect a disease process, a moderate pace of change, close observation, and collaboration among health care professionals trained in both conventional pharmacology and nutritional therapeutics are central to safe and effective application of integrative therapeutics.

Isoniazid

Isoniazid (isonicotinic acid hydrazide, INH; Laniazid, Nydrazid); combination drugs: isoniazid and rifampicin (Rifamate, Rimactane); isoniazid, pyrazinamide, and rifampicin (Rifater).

Isoniazid may interfere with the activity of vitamin E and many other nutrients. Pending further evidence from well-designed clinical trials looking at drug-induced nutrient depletion patterns and compensatory interventions, physicians prescribing isoniazid may want to present patients with the option of using a daily multivitamin/multimineral supplement.

Isotretinoin and Related Retinoids

Acitretin (Soriatane), bexarotene (Targretin), etretinate (Tegison), isotretinoin (13-*cis* retinoic acid; Accutane), tretinoin (all-*trans* retinoic acid, ATRA; Atragen, Avita, Renova, Retin-A, Vesanoid, Vitinoin).

Several potent retinoids deplete vitamin E levels in the skin, which increases the skin toxicity (e.g., cheilosis, drying, The chapping) of these agents. The results of a phase I trial indicate that alpha-tocopherol substantially reduces the initial toxicity of high-dose 13-*cis* retinoic acid (isotretinoin) without compromising drug efficacy.[154] A daily dose of 800 IU alpha-tocopherol has been suggested to reduce retinoid toxicity.[155] In another direction of emerging integrative therapeutics, some clinicians and researchers have been investigating coadministration of 13-*cis* retinoic acid and alpha-tocopherol, often in conjunction with other agents, in the treatment of various cancers recalcitrant to conventional chemotherapy. Several other potent retinoids have also become standard treatments for certain malignancies, such as all-*trans* retinoic acid (etretinate) in acute promyelocytic leukemia, acitretin, and bexarotene for cutaneous T-cell lymphoma (mycosis fungoides), although bexarotene does not have prominent skin toxicity, other than as a photosensitizer. Many clinicians have found that co-prescribing vitamin E (800-1000 IU daily) with these agents reduces their skin toxicity significantly. Large, randomized trials are needed to ensure that there is also no interference with therapeutic efficacy.

Lindane

Lindane (Kwell Shampoo).

Lindane use is associated with a wide range of often significant adverse effects, including promotion of tumor formation.[156] In particular, in vitro studies have found that vitamin E protects human leukocytes against toxic effects of lindane.[157] At this time, evidence is lacking to confirm such protective effects from concomitant use of vitamin E during lindane therapy. However, given that the nutrient is generally considered nontoxic, supplementation at moderate levels during treatment might be judicious.

Mineral Oil

Mineral Oil (Agoral, Kondremul Plain, Liquid Parafin, Milkinol, Neo-Cultol, Petrogalar Plain).

Mineral oil, as a lipid solvent, may also absorb many substances and interfere with normal absorption of alpha-tocopherol and other nutrients.[158] Some disagree, but most researchers have found that mineral oil interferes with the absorption of many nutrients, including beta-carotene, calcium, phosphorus, potassium, and vitamins A, D, K, and E.[159,160] Chronic use of mineral oil may cause a deficiency of these nutrients, the clinical significance of which is as yet undetermined. Individuals taking mineral oil for any extended period may benefit from regular use of a multivitamin supplement that includes all the fat-soluble vitamins. Malabsorption of fat-soluble vitamins from ingestion of mineral oil can also be minimized by administering mineral oil on an empty stomach or consuming vitamin or mineral supplements at least 2 hours before or after the mineral oil. In general, it is advisable to limit the internal use of mineral oil to periods of less than 1 week.

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCept 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).

Use of oral contraceptives (OCs) is associated with increased risk of thrombosis in women, at least in part because of their adverse effects on vitamins and enzymes involved in the oxidative defense system; this risk is known to be significantly elevated by smoking.[161] Susceptibility to lipid peroxidation is greater when antioxidant status is impaired, which may further increase the risk of thrombosis.[162] Supplementation with vitamin E may mitigate some of these adverse effects and elevated risks, although large clinical trials would be necessary to confirm this.

See also Hormone Replacement Therapy.

Paclitaxel

Paclitaxel (Paxene, Taxol).

Paclitaxel monotherapy is not generally associated with significant cardiotoxicity, but it can dramatically increase the cardiac toxicity of anthracyclines such as doxorubicin. In a double-blind pilot study involving 13 cancer patients receiving chemotherapy and 12 patients receiving radiotherapy, Japanese researchers found that an antioxidant regimen (vitamin E, vitamin C, and *N*-acetylcysteine) protected against chemotherapy-induced heart damage without interfering with the action of the primary therapies.[45] Although these preliminary results suggest efficient cardioprotection by this nontoxic and

inexpensive adjunctive supplementation, the study's small size precludes a definitive conclusion. Larger, well-designed clinical trials are warranted for confirmation.

Pentoxifylline

Pentoxifylline (Pentoxil, Trental).

In a clinical trial of 43 patients, presenting with 50 symptomatic radiation-induced fibrosis (RIF) areas involving the skin and underlying tissues, were treated with a combination of pentoxifylline (800 mg/day) and tocopherol (1000 IU/day). Dramatic regression of chronic radiotherapy damage was demonstrated, with all assessable injuries exhibiting continuous clinical regression and functional improvement.[163] Based on these preliminary findings of reversal of human chronic radiotherapy damage, and because no other treatment is presently available for RIF, the researchers concluded that coordinated use of these two agents in a supportive interaction should be considered a therapeutic measure. Further research with larger, well-designed trials is warranted to confirm these findings and develop therapeutic protocols.

Phenobarbital, Phenytoin, Valproic Acid, and Related Anticonvulsant Medications

Carbamazepine (Carbatrol, Tegretol), clonazepam (Klonopin), clorazepate (Tranxene), divalproex semisodium, divalproex sodium (Depakote), ethosuximide (Zarontin), ethotoin (Peganone); felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), levetiracetam (Keppra), mephenytoin, methsuximide (Celontin), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), phenobarbital (Luminal, Phenobarbitone, Solfoton), phenytoin (Dilantin, Phenytek), piracetam (Nootropyl), primidone (Mysoline), sodium valproate (Depacon), topiramate (Topamax), trimethadione (Tridione), valproate semisodium, valproic acid (Depakene, Depakene Syrup), vigabatrin (Sabril), zonisamide (Zonegran).

Two studies conducted by a Japanese research team found lower serum vitamin E levels in individuals taking phenobarbital and phenytoin compared with those who received no anticonvulsant medications for seizures. In the first study, 10 patients undergoing anticonvulsant therapy who had demonstrated low vitamin E levels were then administered dl-alpha-tocopherol acetate, 100 mg/day; after 1 month, both their serum vitamin E levels and hemolysis tests returned to normal, having been abnormal before supplementation.[164] These researchers recommended coadministration with vitamin E for some patients undergoing anticonvulsant therapy. These findings indicate that long-term use of anticonvulsants, particularly phenytoin and phenobarbital, can result in a deficiency of vitamin E, as well as of zinc, which may produce several problems, especially in children.[165] The full clinical implications of this nutrient depletion pattern have yet to be investigated in a large trial, but physicians prescribing anticonvulsant therapy, especially for children, are advised to present the option of supplementing with 100 to 200 IU of vitamin E daily, preferably in a naturally occurring tocopherol form, as prophylaxis against deficiency and its sequelae.

Ramipril and Other Angiotensin-Converting Enzyme (ACE) Inhibitors

Benazepril (Lotensin), captopril (Capoten), cilazapril (Inhibace), enalapril (Vasotec), fosinopril (Monopril), lisinopril (Prinivil, Zestril), moexipril (Univasc), perindopril (Aceon), quinapril (Accupril), ramipril (Altace), trandolapril (Mavik); combination drugs: benazepril and amlodipine (Lotrel); enalapril and felodipine (Lexxel); enalapril and hydrochlorothiazide (Vaseretic); lisinopril and hydrochlorothiazide (Prinzide, Zestoretic).

Long-term data from the Heart Outcomes Prevention Evaluation (HOPE) study might be interpreted to suggest a potential interaction between vitamin E and ramipril (and possibly other ACE inhibitors).[18] In high-risk individuals with diabetes or heart disease undergoing ramipril therapy, concomitant use of vitamin E appears to be associated with increased risk of heart failure. The observed pattern more likely is simply an effect of using large doses of a single antioxidant supplement in patients likely to have high oxidative stress, rather than a true interaction. Until more is known, concomitant use of ACE inhibitors and any single antioxidant nutrient preparation in high doses should be avoided.

Rifampicin

Rifampicin (Rifadin, Rifadin IV); combination drugs: isoniazid and rifampicin (Rifamate, Rimactane); isoniazid, pyrazinamide, and rifampicin (Rifater).

In an in vitro experiment, both vitamin E and rifampicin activated PXR, an orphan nuclear receptor central to xenobiotic metabolism. Production of vitamin E metabolites increased when hepatocytes were incubated with rifampicin and vitamin E (all-racemic alpha-tocopherol). This observation suggests that a CYP3A-type cytochrome initiates tocopherol metabolism by omega oxidation.[166] The clinical implications of this potential interaction are unknown at this time.

Risperidone

Risperidone (Risperdal).

In a case report of a 74-year-old woman being treated for schizoaffective disorder with risperidone, coadministration of vitamins E and B_6 was efficacious in reversing neuroleptic malignant syndrome (NMS), an adverse effect associated with the medication.[167] Although encouraging, further research with well-designed clinical trials into the general effectiveness of adjunctive vitamins E and B_6 to treat (or prevent) NMS in individuals taking risperidone is necessary to confirm these observations and develop therapeutic recommendations.

Verapamil

Verapamil (Calan, Calan SR, Covera-HS, Isoptin, Isoptin SR, Verelan, Verelan PM); combination drug: trandolapril and verapamil (Tarka).

P-glycoprotein (P-gp) mediates resistance of cancer cells to chemotherapy agents that are, or are derived from, natural products. In an in vitro experiment, using a P-gp–expressing human small cell lung cancer line, the inclusion of alpha-tocopherol antagonized the multidrug-resistance (MDR)–modifying ability of verapamil, as well as other chemosensitizing agents, and prevented restoration of sensitivity to both doxorubicin and vinblastine.[65] The clinical implications of such observations in humans are untested and unknown.

Zidovudine (AZT)

Zidovudine (azidothymidine, AZT, ZDV, zidothymidine; Retrovir); combination drugs: zidovudine and lamivudine (Combivir); abacavir, lamivudine, and zidovudine (Trizivir).

In vitro and animal studies indicate that coadministration of AZT and vitamin E (as d-alpha-tocopherol acid succinate) enhanced antiviral activity and therapeutic efficacy, compared with AZT alone.[168] Further research found that this form of vitamin E increased erythroid colony-forming unit (CFU-E)–derived colonies and provided protection against

AZT-induced toxicity to bone marrow at a level equivalent to recombinant human erythropoietin (rhEpo).[169] The clinical significance of such findings has yet to be explored in human trials.

NUTRIENT-NUTRIENT INTERACTIONS

Antioxidants

Vitamin E works synergistically with other antioxidant nutrients to "quench" free radicals, peroxides, and other potentially harmful substances. Antioxidants function best as a network to quench high levels of free radicals safely and effectively. Vitamin E can spare other antioxidants, and vice versa. When given singly, especially at higher dosage levels, antioxidant agents can induce variable antioxidant or pro-oxidant effects in different physiological settings.

Large doses of vitamin E in patients likely to be under oxidative stress (based on their pathology and lifestyle, e.g., smoking, alcohol, recreational drugs) who do not consume a diet rich in antioxidants may contribute to further oxidative stress. In general, individuals with established cardiovascular disease and diabetes represent populations particularly characterized by high oxidative stress. Consequently, long-term daily use of even 400 mg of d-alpha-tocopherol, outside the context of other antioxidant support, by such patients can carry a significant risk that they will produce tocopherol radicals in excess of their ability to quench them. A parallel phenomenon has also been reported with beta-carotene in smokers. This susceptibility applies to all antioxidants, with the possible exception of oligomeric proanthocyanadins (OPCs), and other complex mixtures of flavonoids, such as anthocyanins and anthocyanidin, which contain a variety of compounds with differing redox potentials, and thus have some intrinsic network characteristics. Vitamin E is particularly cardiotrophic and may therefore exert special stress on cardiac tissue. Ultimately, somewhere in the network, a compound is needed that can decompose harmlessly after accepting the electron that has been passed around. A single chemical entity, such as tocopherol or a carotenoid (especially synthetic), usually cannot perform this critical function adequately. Thus, antioxidants are best utilized in a form that maximizes their network effect and minimizes the risk of a paradoxical pro-oxidative effect. At least five antioxidant supplements should be combined, preferably more (e.g., tocopherol, coenzyme Q10, ascorbate, mixed carotenes, vitamin A, selenium, flavonoids). Foods with high ORAC (oxygen radical–absorbing capacity) should always be encouraged in the diet as well.

Chitosan

Chitosan, a supplement proposed to promote weight loss, decreases dietary absorption of fats and therefore also of vitamin E and other fat-soluble nutrients, as shown in an animal model.[170] The clinical significance of this probable pharmacokinetic interaction has yet to be investigated in clinical trials. However, separating intake of therapeutic nutrients such as vitamin E by at least 2 hours before or 4 hours after taking chitosan can avert nutrient depletion in susceptible individuals undergoing long-term use of this nutraceutical.

Iron

Vitamin E can counteract the pro-oxidant activity of iron by, for example, attenuating oxidative stress induced by intravenous iron in patients on hemodialysis.[171] Nevertheless, the mineral can bind and inactivate vitamin E. Vitamin E can also decrease the hematological response to iron salts to a degree that may be clinically significant, particularly in anemic children.[172] Monitoring is warranted.

Polyunsaturated Fatty Acids; Omega-3 and Omega-6 Fatty Acids

High dietary intake of polyunsaturated fatty acids (PUFAs) can induce decreased vitamin E levels.[173] Such long-term dietary patterns require increased vitamin E intake, possibly through supplementation.

Selenium

Selenium potentiates the antioxidant activity of vitamin E. Selenium and vitamin E act synergistically and are more effective when taken together. Among other activities, glutathione peroxidase, the enzyme that recycles oxidized glutathione to its reduced (active) form, is selenium dependent.

Vitamin A

High levels of vitamin E intake may interfere with the absorption of vitamin A.

Vitamin C

Vitamin C facilitates regeneration of vitamin E and restoration of its antioxidant activity, an example of how an antioxidant network functions. Zandi et al.[174] examined data from the Cache County Study, a large, population-based investigation of the prevalence and incidence of Alzheimer's disease and other dementias. They determined that regular use of vitamin E in nutritional supplement doses, especially in combination with vitamin C, may protect the aging brain against pathological changes associated with Alzheimer's disease and reduce the risk of developing the condition. Further study with randomized prevention trials is needed before drawing firm conclusions about the protective effects of such coordinated antioxidant supplementation. If effective, the use of these (and possibly other) antioxidant nutrients may play an important role in a safe and inexpensive strategy for the prevention of Alzheimer's disease.

Bruno et al.[175] have conducted extensive research into the relationship between vitamin C and alpha-tocopherol, with a focus on the conditions of high oxidative stress found in smokers. First, they found that vitamin E "disappearance is accelerated in cigarette smokers due to their increased oxidative stress and is inversely correlated with plasma vitamin C concentrations." Then, in a double-blind, placebo-controlled, randomized crossover trial, Bruno et al.[176] demonstrated that ascorbic acid (500 mg twice daily for weeks) doubled "plasma ascorbic acid concentrations in both groups and attenuated smokers', but not nonsmokers', plasma alpha- and gamma-tocopherol . . . fractional disappearance rates by 25% and 45%, respectively. Likewise, smokers' plasma deuterium-labeled alpha- and gamma-tocopherol concentrations were significantly higher . . . at 72 h during ascorbic acid supplementation compared with placebo." Based on these findings, they concluded that "cigarette smoking increased plasma alpha- and gamma-tocopherol fractional disappearance rates, suggesting that the oxidative stress from smoking oxidizes tocopherols and that plasma ascorbic acid reduces alpha- and gamma-tocopheroxyl radicals to nonoxidized forms, thereby decreasing vitamin E disappearance in humans."[176] Therefore, these investigators confirmed faster plasma vitamin E disappearance in smokers and its normalization with vitamin C administration.

Vitamin K

Vitamin E in high doses may interfere with the absorption and utilization of vitamin K and induce vitamin K deficiency.[124] This potential pattern might be playing a role in cases in which enhanced anticoagulant effect has been reported among patients taking oral anticoagulants following high-dose vitamin E administration. Vitamin E, at levels greater than 1000 IU per day, may alter the activity of vitamin K–dependent clotting factor production and thus coagulation status, possibly increasing the risk of an excessive hypoprothrombinemic response in some individuals on warfarin therapy. (See Warfarin for further discussion.)

The 179 citations for this monograph, as well as additional reference literature, are located under Vitamin E on the CD at the back of the book.

Vitamin K

Nutrient Name: Vitamin K.
Synonyms: Phylloquinone, phytonadione.
Related Substances: Phylloquinone, phytomenadione or phytonadione (K_1), menaquinone (K_2), menadione (K_3).

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Antibiotics ≈≈/≈≈≈/◇/☼	Antibacterial agents can inhibit or eliminate beneficial intestinal flora, thus disrupting gut ecology and interfering with endogenous vitamin K_2 synthesis. Cephalosporins also disrupt synthesis of active clotting factors by inhibiting hepatic vitamin K epoxide reductase. Clinical significance varies with vitamin K status and length of treatment; can be rapid and severe, especially with patients on warfarin therapy.	Administer vitamin K and follow with probiotics. Monitor INR and prothrombin and titrate anticoagulants, if indicated, especially with long-term or repeated antibiotics. Vitamin K administration for excess coumadin effect should be done only by practitioners experienced in this maneuver.
Bile acid sequestrants Cholestyramine, colestipol ≈≈≈	Bile acid sequestrants interfere with absorption of vitamin K and other fat-soluble nutrients. Consensus on mechanism; clinical significance variable, but more important for those with higher cardiovascular risk.	Supplement vitamin K, as well as mixed tocopherols, coenzyme Q10 and other fat-soluble nutrients important for cardiovascular health.
Corticosteroids, oral Prednisone ☼/≈≈≈	Oral corticosteroids can cause increased urinary loss of vitamin K as well as depletion of other key nutrients. Long-term oral steroid use may lead to clinically significant depletion, particularly affecting bone mass; may be prevented or reversed with vitamin K administration, especially in conjunction with synergistic nutrients.	Coadminister vitamin K (may require menatetrenone, a form of K_2), and monitor for bone loss, especially BMD, with extended steroid therapy.
Phenytoin, phenobarbital Anticonvulsant medications ≈≈≈/◇◇	Many anticonvulsants increase breakdown of vitamin K by inducing hepatic microsomal oxidase enzymes. Clinical significance unclear; greatest in pregnancy.	Coadminister vitamin K (possibly IM), especially during pregnancy.
Mineral oil ≈≈≈	Mineral oil may interfere with absorption of vitamin K and other nutrients. Evidence minimal but effect probable, though of variable clinical significance. Malabsorption of vitamin K can increase anticoagulant activity of warfarin.	Supplement with vitamin K–containing multivitamin; separate intake. Avoid extended intake of mineral oil. Monitor and titrate with concomitant warfarin
Warfarin Oral vitamin K antagonist anticoagulants ◇◇/⊕X/◇◇	Warfarin and indandione anticoagulants act by inhibiting conversion of the vitamin K epoxide back to vitamin K. Excessive vitamin K intake, directly or within foods or herbs, will interfere with therapeutic action unless closely monitored, dose-titrated, and properly managed within comprehensive therapeutic strategy. Adverse effects can be rapid and serious. Close management, multidisciplinary collaboration, and active patient dialogue essential.	Limit and tightly regulate vitamin K intake. Closely monitor INR and titrate anticoagulant at close intervals when administering herbs, nutrients, or foods with substantial K content.

INR, international normalized ratio; IM, intramuscularly; BMD, bone mineral density.

NUTRIENT DESCRIPTION

Chemistry and Forms

Vitamin K refers to a family of compounds exhibiting the activity of phytomenadione. Phylloquinone (or phytomenadione) is the K_1 form naturally occurring in plants and fish. Bacteria synthesize menaquinone (K_2), a fat-soluble form. Menadione (K_3), the water-soluble parent compound, does not occur naturally.

Physiology and Function

Vitamin K serves as a coenzyme during the synthesis of many proteins involved in blood clotting and bone metabolism. Vitamin K_1 is fat soluble and requires bile salts for absorption in the upper gastrointestinal tract. Vitamin K acts as a cofactor in the final synthesis of proteins with a modified amino acid residue. This modified glutamic acid residue is found in the blood and along vessel walls, along with platelet-derived phospholipid, where it binds and facilitates the action of calcium, and is an integral part of the clotting process. It is also found in bone proteins and can bind onto calcium ions to cause calcification. This role in calcium transport is central to vitamin K's functions within healthy bone formation and blood clotting.

Vitamin K enables both coagulation and fibrinolysis. Vitamin K's central role in blood coagulation involves synthesis of coagulation components, such as prothrombin (factor II), as well as factors VII, IX, and X and proteins C, S, and Z in the liver. Proteins C and S promote fibrinolysis and anticoagulation. Thus, they are involved with reducing inflammation.

Osteocalcin, matrix Gla protein, and protein S are vitamin K–dependent structural and regulatory proteins in bone and vascular metabolism. Vitamin K plays the critical role of allowing calcium ions to bind, thus resulting in the calcification of bone. Osteocalcin metabolism has been implicated in the pathogenesis of osteoporosis through an unknown mechanism that may be linked to suboptimal vitamin K status, resulting in its undercarboxylation and presumed dysfunction.

Probiotic microflora in the intestines, when a healthy microecology is functioning, normally manufacture significant amounts of vitamin K, contributing up to half of daily requirements in some individuals.

NUTRIENT IN CLINICAL PRACTICE

Historical/Ethnomedicine Precedent

In most cultural traditions, herbs and green leafy vegetables have historically been used to enrich and tonify the blood and support its metabolic functions. Consumption of cultured foods can support vigorous probiotic flora population and healthy gut ecology.

Possible Uses

Acute myeloid leukemia (vitamin K_2 only), bone loss (risk reduction), calcium oxalate kidney stones (prevention), celiac disease (malabsorption-induced deficiency), coagulation disorders, cystic fibrosis, epistaxis, floaters (in eyes), fractures (risk reduction), gastric bypass with Roux-en-Y (bariatric surgery), hemorrhagic disease of the newborn, inflammatory conditions, myelodysplastic syndromes (vitamin K_2 only), nausea and vomiting of pregnancy, osteoporosis, phenylketonuria (if deficient), preterm infants (K_1 prophylaxis), pruritus, rheumatoid arthritis, stroke prevention; vitamin K malabsorption (e.g., with celiac disease or bariatric surgery), warfarin overanticoagulation.

When the clotting mechanism is disrupted by medications such as certain antibiotics, cephalosporin possessing an MTT side chain, or excessive doses of oral anticoagulants (warfarin), vitamin K can be administered to correct the situation.

Deficiency

Symptoms: Easy bruising, small amounts of blood in stool, prolonged bleeding; impaired bone remodeling, and mineralization.

Vitamin K deficiency is rare in the general population, but the risk is significantly greater in infants, especially premature infants and those who are exclusively breast-fed, for whom such a deficiency can be fatal (hemorrhagic disease of the newborn). Adults at increased risk of vitamin K deficiency include individuals with heavy alcohol intake, liver disease, fat malabsorption, or chronic digestive disorders, such as chronic diarrhea, celiac sprue, Crohn's disease or ulcerative colitis, and bariatric surgical procedures that bypass the duodenum.

In recent years, several published papers suggest that the dietary reference intakes (DRIs) for vitamin K are based solely on levels relevant to hepatic synthesis of clotting factors, and that much higher levels (10 mg/day) may be needed for optimal health of the skeletal and vascular systems. Vascular calcification may be related to chronic insufficiency of vitamin K intake. Patients receiving chronic warfarin, essentially an induced vitamin K deficiency, have a higher incidence of vascular calcification.

Dietary Sources

Leafy green vegetables are the single best dietary source of vitamin K because of their high chlorophyll content; the vitamin K content is proportionate to the degree to which the plant parts are green. Kale, green tea, and turnip greens are the most abundant food sources. Spinach, broccoli, lettuce, and cabbage are also rich sources. Other food sources include egg yolk, cow's milk, and liver, as well as soybean oil, olive oil, cottonseed oil, and canola oil.

The probiotic flora inhabiting intestines with a healthy ecology normally manufacture vitamin K_2, or ***menaquinone***. Menaquinones (MK-*n*, with the *n* determined by the number of prenyl side chains) can also be found in the diet; MK-4 is in meat, and MK-7, -8, and -9 are found in fermented food products such as cheese. The Japanese fermented soy product ***natto*** is a rich source of MK-7. Some sources have said that MK-4, also known as ***menatetrenone***, is synthetic vitamin K_2, but this is not accurate. However, MK-4 is distinct from other MKs because it is not produced in significant amounts by gut microflora, but it can be derived from vitamin K_1 in vivo. Hydrogenation of plant oils appears to decrease the absorption and biological effect of vitamin K in bone, possibly as an effect of *trans*-fatty acids.

Nutrient Preparations Available

Phylloquinone (K_1) is the usual form of supplemental vitamin K. Vitamin K_2 is also used therapeutically, often parenterally. Mixed K_1 and K_2 formulations are increasingly available. The natural, long-chain menaquinone-7 (MK-7), derived from natto, exhibits a "very long half-life time,... resulting in much more stable serum levels and accumulation of MK-7 to higher levels (7-8 fold) during prolonged intake,"[1] compared to synthetic vitamin K_1. The MK-7 preparation can also induce "more complete carboxylation of osteocalcin," and thereby also increase activity against vitamin K antagonists.[1]

Dosage Forms Available

Capsule, tablet; injectable (prescription only).

Dosage Range

Adult

Supplemental/Maintenance: 30 to 100 µg per day.
Pharmacological/Therapeutic: 45 to 500 µg per day.
Toxic: None reported or suspected.

Pediatric (<18 years)

Supplemental/Maintenance
- Infants, birth to 6 months: 5 µg/day
- Infants, 7 to 12 months: 10 µg/day
- Children, 1 to 3 years: 15 µg/day
- Children, 4 to 6 years: 20 µg/day
- Children, 7 to 10 years: 30 µg/day

Pharmacological/Therapeutic: 45 to 150 µg per day.
Toxic: None reported or suspected.

Laboratory Values

Plasma vitamin K: Osteocalcin level is sometimes used as a surrogate test for vitamin K status.

Prothrombin time (PT) and clotting factors (X, IX, VII, and protein C) may also be used as reference values, but PT is not considered a reliable test for vitamin K status. Vitamin K deficiency will prolong PT, but so does hepatic insufficiency (which also results in inadequate levels of clotting factors).

SAFETY PROFILE

Overview

Supplemental vitamin K is generally considered safe when used in accordance with proper dosing guidelines. No adverse effects associated with vitamin K consumption from food or supplements have been reported in humans or animals. This does not mean, however, that no potential exists for adverse effects resulting from high intakes beyond normal dietary or supplemental levels. Because data on the adverse effects of vitamin K are limited, caution may be warranted.

Patients undergoing anticoagulant therapy should monitor vitamin K intake and avoid significant inconsistencies in intake levels. Regular monitoring of coagulation parameters (INR) and dose titration is essential.

Nutrient Adverse Effects

General Adverse Effects

Naturally occurring vitamin K_1 (phylloquinone) is generally considered nontoxic, whereas menadione (K_3), the synthetic derivative, has been associated with potentially severe toxicity reactions at high doses, particularly in infants and other highly vulnerable populations. Flushing and perspiration are the most common, although infrequent, adverse effects reported. Other potential toxicity symptoms include difficulty breathing, tightness in throat or chest, chest pain, hives, rash, or itchy or swollen skin. Rare cases of hemolytic anemia have been reported.

The primary risk associated with vitamin K has been limited to rare reports of cutaneous allergic reaction to intramuscular (IM) vitamin K_1.

Less than 1%: Abnormal taste, anaphylaxis, cyanosis, diaphoresis, dizziness (rarely), dyspnea, gastrointestinal upset (oral), hemolysis in neonates and in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, hypersensitivity reactions, hypotension (rarely), pain, tenderness at injection site, transient flushing reaction.

More recently, discussions have arisen concerning potential risk of cirrhosis associated with supplemental intake of vitamin K, but not with food sources, in the treatment of osteoporosis.

Toxicity

Phylloquinone (vitamin K_1) is not toxic at 500 times the recommended dietary allowance (RDA, 0.5 mg/kg/day). No toxicities have been reported or suspected as being associated with natural vitamin K at any dose in humans when given orally. Intravenous (IV) administration of vitamin K at doses of 2 to 8 mg/kg has been found to be lethal in horses.

Menadione (vitamin K_3) has a finite toxicity resulting from its reaction with sulfhydryl groups. Large doses of menadione may produce hemolytic anemia, hyperbilirubinemia, and kernicterus in the infant. Other signs of synthetic vitamin K toxicity include flushing, sweating, and chest constriction. Most toxicity is associated with IV use and may be related to allergies to various preservatives or excipients.

Adverse Effects Among Specific Populations

Patients receiving anticoagulant therapy should monitor vitamin K intake. Possible risk of aggravation exists among individuals prone to form kidney stones.

Pregnancy and Nursing

No extant reports of adverse effects have been related to fetal development during pregnancy. This fat-soluble vitamin crosses the placenta and is excreted into breast milk.

Infants and Children

Vitamin K can cause a fatal form of jaundice in infants. No adverse effects have been reported among breast-fed infants.

Contraindications

Patients undergoing anti–vitamin K anticoagulant therapy, except within the context of appropriate professional supervision; some premature infants.

INTERACTIONS REVIEW

Strategic Considerations

The primary interactions of clinical significance involving vitamin K and pharmaceutical agents derive from interference of vitamin K with the therapeutic action of certain anticoagulant medications and the adverse effect of antimicrobial medications on normal vitamin K synthesis by gut bacterial flora. Although vitamin K's role in coagulation receives attention regularly, its influence on fibrinolysis also needs to be considered. The critical issue with anticoagulants is monitoring and managing the proportionate effects of the medication and dietary or supplemental sources of vitamin K. Strategic administration of probiotic flora and restoration of a healthy gut ecology can compensate for the tactical use of antimicrobial agents in the suppression of infectious bacteria. The interactions involving vitamin K provide challenging opportunities for reframing the constituent elements of medical intervention within the context of a dynamic and evolving individualized process emphasizing strategic goals and comprehensive clinical outcomes, such as improved function, decreased risk, and enhanced quality of life.

Oral Anticoagulant Overdose

Clinical surveys have found that a substantial number of anticoagulation clinics underutilize oral phytonadione for patients with supratherapeutic international normalized ratio (INR) values. These data indicate that such clinics do not comply with the guidelines for vitamin K use developed at the American College of Chest Physicians (ACCP) Fifth Consensus Conference on Antithrombotic Therapy, as published in 1998.

NUTRIENT-DRUG INTERACTIONS

Antibiotics/Antimicrobial Agents (Systemic)

Aminoglycoside Antibiotics: Amikacin (Amikin), gentamicin (G-mycin, Garamycin, Jenamicin), kanamycin (Kantrex), neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin), netilmicin (Netromycin), paromomycin (monomycin; Humatin), streptomycin, tobramycin (AKTob, Nebcin, TOBI, TOBI Solution, TobraDex, Tobrex).

Beta-Lactam Antibiotics: Methicillin (Staphcillin); aztreonam (Azactam injection); carbapenem antibiotics: meropenem (Merrem I.V.); combination drug: imipenem and cilastatin (Primaxin I.M., Primaxin I.V.); penicillin antibiotics: amoxicillin (Amoxicot, Amoxil, Moxilin, Trimox, Wymox); combination drug: amoxicillin and clavulanic acid (Augmentin, Augmentin XR, Clavulin); ampicillin (Amficot, Omnipen, Principen, Totacillin); combination drug: ampicillin and sulbactam (Unisyn); bacampicillin (Spectrobid), carbenicillin (Geocillin), cloxacillin (Cloxapen), dicloxacillin (Dynapen, Dycill), mezlocillin (Mezlin), nafcillin (Unipen), oxacillin (Bactocill), penicillin G (Bicillin C-R, Bicillin L-A, Pfizerpen, Truxcillin), penicillin V (Beepen-VK, Betapen-VK, Ledercillin VK, Pen-Vee K, Robicillin VK, Suspen, Truxcillin VK, V-Cillin K, Veetids), piperacillin (Pipracil); combination drug: piperacillin and tazobactam (Zosyn); ticarcillin (Ticar); combination drug: ticarcillin and clavulanate (Timentin).

Cephalosporin Antibiotics: Cefaclor (Ceclor), cefadroxil (Duricef), cefamandole (Mandol), cefazolin (Ancef, Kefzol), cefdinir (Omnicef), cefepime (Maxipime), cefixime (Suprax), cefoperazone (Cefobid), cefotaxime (Claforan), cefotetan (Cefotan), cefoxitin (Mefoxin), cefpodoxime (Vantin), cefprozil (Cefzil), ceftazidime (Ceptaz, Fortaz, Tazicef, Tazidime), ceftibuten (Cedax), ceftizoxime (Cefizox), ceftriaxone (Rocephin), cefuroxime (Ceftin, Kefurox, Zinacef), cephalexin (Keflex, Keftab), cephapirin (Cefadyl), cephradine (Anspor, Velocef); imipenem combination drug: imipenem

and cilastatin (Primaxin I.M., Primaxin I.V.); loracarbef (Lorabid), meropenem (Merrem I.V.).

Fluoroquinolone (4-Quinolone) Antibiotics: Cinoxacin (Cinobac, Pulvules), ciprofloxacin (Ciloxan, Cipro), enoxacin (Penetrex), gatifloxacin (Tequin), levofloxacin (Levaquin), lomefloxacin (Maxaquin), moxifloxacin (Avelox), nalidixic acid (Neggram), norfloxacin (Noroxin), ofloxacin (Floxin, Ocuflox), sparfloxacin (Zagam), trovafloxacin (alatrofloxacin; Trovan).

Macrolide Antibiotics: Azithromycin (Zithromax), clarithromycin (Biaxin), dirithromycin (Dynabac), erythromycin, oral (EES, EryPed, Ery-Tab, PCE Dispertab, Pediazole), troleandomycin (Tao).

Sulfonamide Antibiotics: Sodium sulfacetamide (AK-Sulf, Bleph-10, Sodium Sulamyd), sulfamethoxazole (Gantanol), sulfanilamide (AVC), sulfasalazine (Salazosulfapyridine, salicylazosulfapyridine, suphasalazine; Apo-Sulfasalazine, Azulfidine, Azulfidine EN-Tabs, PMS-Sulfasalazine, Salazopyrin, Salazopyrin EN-Tabs, SAS), sulfisoxazole (Gantrisin); combination drug: sulfamethoxazole and trimethoprim (cotrimoxazole, co-trimoxazole, SXT, TMP-SMX, TMP-sulfa; Bactrim, Bactrim DS, Cotrim, Septra, Septra DS, Sulfatrim, Uroplus); triple sulfa (Sultrin Triple Sulfa).

Chemotherapy, Cytotoxic Antibiotics: Bleomycin (Blenoxane), dactinomycin (Actinomycin D, Cosmegen, Cosmegen Lyovac), mitomycin (Mutamycin), plicamycin (Mithracin).

Miscellaneous Antibiotics/Antimicrobials: Bacitracin (Baci-IM), chloramphenicol (Chloromycetin), chlorhexidine (Peridex), clindamycin, oral (Cleocin), colistimethate (Coly-Mycin M), dapsone (DDS, diaminodiphenylsulphone; Aczone Gel, Avlosulfon), furazolidone (Furoxone), lincomycin (Lincocin), linezolid (Zyvox), nitrofurantoin (Macrobid, Macrodantin), trimethoprim (Proloprim, Trimpex), vancomycin (Vancocin).

Effect and Mechanism of Action

Antimicrobial therapies, particularly chronic or recurrent courses of treatment, exert a detrimental and often devastating effect on beneficial bacterial flora naturally populating the human digestive tract. The diverse microorganisms comprising the gut microflora play a critical role in the synthesis of vitamin K, as well as synthesis of the B vitamins and the metabolism of bile acids, other sterols, and xenobiotics.[2,3] Broad-spectrum antibiotics reduce hepatic vitamin K_2 (menaquinone) stores, presumably by reducing its synthesis by gut microflora.[4-7] In relation to warfarin, the INR reflects the balance between the anticoagulant and vitamin K. When the intestinal flora are wiped out by antibiotics, their production of vitamin K diminishes, and the INR increases. Some antibiotics, particularly trimethoprim/sulfamethoxazole (Bactrim, Septra), and fluoroquinolones to a slightly lesser degree, specifically increase warfarin effect independent of their effect on bacterial flora production of vitamin K, by displacing it from protein-binding sites and dramatically elevating the anticoagulant effect.

In particular, in addition to reducing bacterial vitamin K synthesis, cephalosporins containing an *N*-methylthiotetrazole (MTT) side chain can result in a clinically relevant coagulopathy, prolonged PT, and increased risk of bleeding complications because of a deficiency in active vitamin K–dependent clotting factors.[5,8-11] In particular, cephalosporins such as cefazolin, cefmetazole, cefoperazone, and cefotetan, which feature the MTT side chain, can cause vitamin K deficiency and hypoprothrombinemia, disrupting synthesis of active clotting factors by inhibiting hepatic vitamin K *epoxide reductase* (ER), an enzyme necessary to recycle vitamin K back to its active form.[12,13] Even so, in a study using dogs, Spurling et al.[9] found that cefuroxime, which lacks the MTT side chain, still appears to affect PT by reducing bacterial vitamin K synthesis. Other evidence indicates that antibiotics other than MTT–side chain cephalosporins may also act as weak inhibitors of the vitamin K epoxide cycle.

Research

During the past decade the scientific literature investigating probiotic intestinal flora has grown exponentially and with it a deeper appreciation of the clinical significance of these symbiotic microorganisms in healthy human physiology. The unintended adverse effects of antibiotics on gut flora will impact most individuals to some degree, but such actions pose a potentially significant risk to individuals living within tight parameters of vitamin K regulation via anticoagulant medications. Early animal studies led by Spurling, Shirakawa, and others found that deliberate destruction of intestinal flora induced a measurable decrease in vitamin K levels and amplified alterations in coagulation functions, including prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT).[4-9] A subsequent review by Lipsky[14] (1994) criticized some of the assertions used in previous studies and asserted that there was no definitive evidence that intestinal bacteria were an important source of vitamin K. Some later review articles, such as Covington, have claimed that antibiotic use infrequently causes significant disruption to gut flora and thus vitamin K. Although transient interference with flora vitamin K synthesis may not trigger clinically significant perturbations in plasma vitamin K levels, high doses of broad-spectrum antibiotics, especially in a repeated or chronic prescribing pattern, may fundamentally undermine the dynamic infrastructure of endogenous menaquinone synthesis.

Amid this controversy, an emerging body of reports and research have documented proposed, and discovered further, critical and irreplaceable functions of bacterial flora in the microecology of the digestive tract in relation to nutrient assimilation, transformation, and synthesis; immune function; infection resistance; detoxification; neurotransmitter function; hormonal regulation; and numerous other systemic functions. Along with the emergence of antibiotic-resistant bacterial strains, the often-indiscriminate and hasty overprescribing of antibiotics has contributed to systematic eradication of beneficial bacterial flora en masse, with no equally programmatic conventions for probiotic replacement. Further, growing research has demonstrated the importance of prebiotic substances that aim at stimulating the growth of such flora, thus modulating the composition of the natural ecosystem.

In recent years, increasing attention has focused on the possible beneficial effects of prebiotics, such as enhanced resistance to invading pathogens, improved bowel function, anti–colon cancer properties, lipid-lowering action, and improved calcium bioavailability.[15–20]

Thus, an emerging consensus of evidence indicates that these broad adverse effects are responsible for a disturbing pattern of apparent interactions between warfarin and antibiotics that do not seem to result from pharmacokinetics or other direct interaction, but rather from the destruction of gut flora and the ecosystem of which they are a part. Therefore, the initial dose of warfarin arrived at to bring the INR into the target therapeutic range always needs to be analyzed in the context of body stores, endogenous synthesis, and dietary intake of K_1 and synthesized K_2. If individuals have low stores and little endogenous synthesis, they will be "coumadin sensitive"; that is, a few milligrams will put them into therapeutic range. Conversely, only the change in the vitamin K status (or vitamin K ER function) creates an unstable INR situation. Thus, the state of an individual's intestinal ecology may not affect the ability to titrate to a stable INR, but someone with significant "dysbiosis" (i.e., disrupted gut ecology and attendant dysfunctions) may be started on 5 mg of coumadin and have an INR of 7 within a few days, potentially leading to an exaggerated or misunderstood perception of the overall situation by the physician.

Apart from consideration of general trends, the potential for disruption of vitamin K concentrations and coagulation functions subsequent to antibiotic administration warrants higher levels of monitoring and management than previously considered necessary in conventional practice. Olson[21] noted in 1999 that a reduction in prothrombin and other vitamin K–dependent factors can indicate a deficiency. In a comprehensive review (2000) of vitamin K and vitamin K antagonists Vermeer and Schurgers[22] further observed that severe vitamin K deficiency may be associated with detectable plasma levels of descarboxyprothrombin. The body of evidence suggests that any such decline in vitamin K status attributable to antibiotic effects on endogenous flora will carry a greater risk of contributing to a clinically significant disruption in coagulation stability in individuals with preexisting low vitamin K levels, suffering from renal failure, or recovering from organ transplant surgery.

Ofloxacin represents one notable, but partial, exception to the general concern regarding the action of antibiotics as a class in relation to interference with the vitamin K–dependent coagulation factors. In a small, preliminary study with seven healthy male subjects, Verho et al.[23] observed that ofloxacin, 200 mg once daily for 7 days, did not alter the anticoagulant response to phenprocoumon after a stabilization phase of 2 weeks. If subsequent research were to confirm this finding, individuals taking ofloxacin might not need to supplement vitamin K to protect against possible drug-induced depletion. Nevertheless, the indirect effect of ofloxacin on vitamin K synthesis by intestinal flora would remain an issue of concern and worthy of specific inquiry through clinical trials.

Reports

As clinicians and researchers have become increasingly aware of the multifaceted roles of intestinal microflora, there has been a steady rise in reports documenting interactions between anticoagulant medications, especially warfarin, and a range of antibiotic medications, which appear to be more widespread and deleterious than would be attributable to predictable pharmacokinetics and other direct mechanisms of interaction. In an innovative research methodology comparing postmortem liver tissue from 22 deceased patients, nine of whom had been given broad-spectrum antibiotics before death, Conly and Stein[7] observed a reduction in hepatic bacteria-produced menaquinone (K_2) concentration associated with the use of such antimicrobials; in contrast, there was a lack of significant difference in hepatic levels of dietary-derived phylloquinone between the two groups.[24] A 1996 case report by Bandrowsky et al.[25] documented significant postoperative bleeding caused by an amoxicillin-induced vitamin K deficiency, rather than a failure of the local tranexamic acid mouth rinse protocol being applied. In a review, Huilgol et al.[26] reported a case of antibiotic-induced vitamin K deficiency that resulted in hemobilia (bleeding into the biliary tract) complicating acalculous cholecystitis. Suzuki et al.[27] reported on an infant with intracranial hemorrhage, 2 days after the introduction of oral antibiotics, which was attributed to vitamin K deficiency despite K_3 prophylaxis. In 2002, Jones and Fugate[28] published four case reports demonstrating significant elevations in INR values during and up to 1 day after levofloxacin therapy in previously stable patients undergoing warfarin therapy. The authors attributed this unexpected interaction to displacement of warfarin from protein-binding sites, reduction in gut flora producing vitamin K, and decreased warfarin metabolism. In 2003, Davydov et al.[29] reported the case of a 58-year-old woman who developed an elevated INR and microscopic hematuria after taking amoxicillin/clavulanate potassium while on warfarin therapy. They concluded that a decrease in vitamin K–producing gut flora with resulting vitamin K deficiency was the most likely contributing factor.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although the practice of regularly replacing probiotic flora after the use of antibiotics has been widespread in European and natural medicine for decades, integration of such prescribing practices has only recently entered mainstream practice of conventional medicine in the United States as the evidence of the importance of such flora and gut ecology has accumulated. A wide range of evidence demonstrates multifaceted benefits from recolonization of symbiotic microflora and reestablishment of a vigorous gut ecology after antibiotic therapy for the general population. The clinical significance of such replacement theraphy may be greater among individuals undergoing warfarin or other vitamin K–oriented anticoagulant therapy as a result of the antibiotic's adverse impact on normal intestinal microorganisms. Preventive supplementation is warranted, particularly in nutritionally deficient or otherwise-compromised individuals, but the administration of probiotics would be especially appropriate for individuals with known or potential coagulation disorders manifesting hypoprothrombinemia, with internal and external hemorrhage or other signs and symptoms of deficiency. Among the agents discussed, cephalosporins are most likely associated with vitamin K deficiency. Quinolones and sulfonamides have further interactions complications of clinical significance in addition to the flora-depletion issues inherent to other antibiotic medications.

Conservative nutritional practice indicates the value of supplementing with vitamin K whenever an antibiotic medication is used. A daily dosage of 45 to 80 μg of vitamin K along with administration of diverse and vigorous cultures of probiotic flora, during and for a minimum of 2 weeks after the course of antibiotics, will generally be adequate to mitigate any disruptive effects on gut ecology and vitamin K synthesis. Although such combinations are available, most multivitamin formulations do not contain either vitamin K or probiotics. Further variables in the patient's clinical presentation, serum levels, age, gender, dietary habits, and medication regimen can

be considered in crafting the therapeutic protocol to best support the broader strategic agenda. Regular monitoring and close clinical management are important during any vitamin K administration or recolonization of beneficial flora in patients taking vitamin K antagonist anticoagulants, such as warfarin. Just as production of vitamin K diminishes and the INR increases as the intestinal flora are damaged or eliminated by antibiotics, so, conversely, can their reintroduction shift the relationship between vitamin K and anticoagulant medications, especially warfarin. Until probiotic replacement can restore and maintain this balance, it is usually necessary to reduce the dose of warfarin during a course of antibiotics. During coadministration of probiotics and warfarin, the anticoagulant dose may need to be titrated, realizing that the effects of a dose adjustment on a given day will be seen in the INR 2 days later. Whenever possible, it can be beneficial for patients undergoing warfarin therapy to have a home monitor so that they can monitor their INR daily during such situations. As previously noted, different antibiotics appear to exert widely varying levels of effect on vitamin K activity, both directly and through effects on flora, so the urgency and scale of the clinical response can vary significantly based on the medication being administered as well as other factors relating to the individual characteristics of the patient. If hemorrhage occurs subsequent to antibiotic therapy, medical intervention is appropriate. In such cases, vitamin K should initially be administered by IM injection, or in urgent cases, a low dose of vitamin K_1, such as 0.5 mg, can be infused intravenously over 30 minutes.

Replacement therapy with exogenous probiotics subsequent to antimicrobial medications should be paced in individuals undergoing anticoagulant therapy, given the potential for increased endogenous production of vitamin K_2 by the resurgent ecology. Again, the effects of such administration are more likely to be significant with neonates and in individuals who have been nutritionally deficient in vitamin K. Even so, daily intake of vitamin K from a balanced and nutritious diet is usually greater than the levels produced by active flora. Additional research is warranted to better determine the particular dosages of vitamin K supplementation and probiotic replacement appropriate to respective antibiotic medications, particularly in the context of anticoagulant therapy. However, the availability of oral, direct thrombin inhibitors, such as Exanta (Astra-Zeneca), may soon reduce the risk of drug interactions and the need to restrict vitamin K intake, as well as provide a sufficiently predictable effect that monitoring is unnecessary.

Bile Acid Sequestrants

Cholestyramine (Locholest, Prevalite, Questran), colesevelam (WelChol), colestipol (Colestid).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **3. Possible**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Bile acid sequestrants, such as cholestyramine and colestipol, are designed to prevent bile acids from being reabsorbed and recycled by the enterohepatic circulation, thus forcing the body to metabolize reserves of cholesterol into more bile acids. Because bile acids and their salts are used to solubilize and absorb many fat-soluble nutrients, as a direct consequence such sequestrants may also interfere with absorption of vitamin K and other fat-soluble nutrients, including vitamins A, D, and E; carotenoids; essential fatty acids; and lipid-soluble antioxidants, such as coenzyme Q10.[30-36]

Research

Clinical studies and research reviews consistently acknowledge the high probability of vitamin K malabsorption resulting from bile acid sequestrants. Opinions have varied as to the clinical significance of such drug-induced depletion patterns; the general trend has been toward deeper appreciation of the importance of nutrients such as vitamin K and a growing awareness of the subtle and pervasive adverse effects resulting from such interference with normal nutritional intake and metabolism over time.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Vitamin K supplementation, as part of a multivitamin-mineral formulation, would probably be of benefit for individuals taking bile acid sequestrants. Taking such supplements daily, at least 1 hour before or 4 to 6 hours after the medication, will reduce the degree of interference with the intended nutriture.

Nevertheless, this interaction raises serious questions about continuity between tactical methods of specific interventions and strategic goals of improved health, reduced risk, and better outcomes, given the accumulating experimental, epidemiological, and clinical evidence of an association between nutrient intake and reduced risk of coronary heart disease.

Corticosteroids, Oral, Including Prednisone

Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol) prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **3. Possible**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Vitamin K plays a key role in calcium transport and enhances bone formation. Oral corticosteroids can cause increased urinary loss of vitamin K, as well as of vitamin C, selenium, and zinc. Steroidal medications are also well known to enhance bone resorption and suppress bone formation, leading to loss of bone mineral density (BMD) and potentially to developmental problems and osteoporosis.

Research

Numerous studies examining the relationship between vitamin K status and osteoporosis have demonstrated the critical role played by the nutrient in maintaining and restoring bone health.[37] Other researchers have focused on the therapeutic benefits that vitamin K supplementation might provide to individuals whose bone health was likely to be compromised, particularly by iatrogenic loss of BMD. Yonemura et al.[38] conducted a small clinical trail investigating the short-term effect of vitamin K administration (as menatetrenone) on

prednisolone-induced loss of BMD in 20 patients with chronic glomerulonephritis. Ten patients received prednisolone alone, and the other 10 patients received prednisolone plus 15 mg of menatetrenone three times daily. Their findings confirmed that prednisolone resulted in loss of BMD of the lumbar spine associated with suppression of both bone formation and enhancement of bone resorption, and that such prednisolone-induced reduction of BMD was prevented by menatetrenone administration.

Inoue et al.[39] conducted a prospective pilot study focusing on the important issue of adverse effects on skeletal development and bone health in children undergoing glucocorticoid therapy. Twenty children were divided in to two groups; one group received alfacalcidol (0.03 μg/kg/day) and the other alfacalcidol (0.03 μg/kg/day) plus menatetrenone (~2 mg/kg/day) for 24 weeks. Bone biochemical markers and BMD were measured at baseline and after treatment. The authors concluded that that menatetrenone effectively and safely increases lumbar BMD, probably through carboxylation of osteocalcin, in long-term prednisolone-treated children receiving alfacalcidol who have a high bone turnover; no adverse effects were observed.

Uncertainty remains as to the comprehensive processes and mechanisms of action involved in bone loss and protection against such unintended adverse effects, particularly the clinical significance of increased nutrient loss through urination resulting from steroids. Most likely, variables of age, gender, health status, and conditions being treated will all influence the degree to which urinary loss of vitamin K directly impacts BMD and increases risk of bone loss. These small, short-term studies suggest that large, well-designed, randomized, double-blind controlled trials focusing on different populations are warranted to understand better the physiological processes and risk factors involved and to develop responsive therapeutic protocols.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Individuals receiving oral corticosteroid therapy for extended periods will most likely benefit from increased vitamin K intake, whether supplemental or dietary. The studies cited and other research have involved physician-administered forms of vitamin K. Further research investigating food sources of vitamin K or oral forms of vitamin K suitable for self-care deserve attention because therapeutic levels of vitamin K are typically obtainable by such means. Given that this nutrient has small risk of adverse effects or toxicity, such supplementation could easily fit within the monitoring and supervision inherent to steroid therapy.

Topical and inhaled corticosteroids have generally been found to exert significantly lesser adverse effects on BMD. Therefore, patients receiving such therapy would be less likely to benefit from vitamin K supplementation.[40-42]

Mineral Oil

Mineral oil (Agoral, Kondremul Plain, Liquid Parafin, Milkinol, Neo-Cultol, Petrogalar Plain).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary,** possibly
◉ **Emerging**

Effect and Mechanism of Action

Mineral oil, as a lipid solvent, may absorb many substances and interfere with normal absorption of vitamin K and other nutrients. The sequelae of such effects can alter the activity of anticoagulant medications through reduced vitamin K levels.

Research

Although some disagree, most researchers have found that mineral oil interferes with the absorption of many fat-soluble nutrients, including beta-carotene, calcium, phosphorus, potassium, and vitamins A, D, K, and E.[43,44] Chronic use of mineral oil can cause a deficiency of vitamins A, D, E, and K, being fat soluble, because these vitamins are dissolved in the mineral oil, which is not absorbed from the intestine. This is especially problematic during pregnancy since the regular ingestion of mineral oil may reduce the assimilation of critical nutrients. The malabsorption of vitamin K can result in an increased anticoagulant activity by warfarin anticoagulants because of this adverse effect of mineral oil.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Individuals using mineral oil for any extended period will likely benefit from regular use of a multivitamin supplement containing more than 100 μg of vitamin K per daily dose. Malabsorption of fat-soluble vitamins caused by ingestion of mineral oil can be minimized by administering mineral oil on an empty stomach or consuming vitamin or mineral supplements at least 2 hours before or after the mineral oil. In general, it is advisable to limit the internal use of mineral oil to less than 1 week.

Phenytoin, Phenobarbital, and Other Anticonvulsant Medications

Carbamazepine (Carbatrol, Tegretol), clonazepam (Klonopin), clorazepate (Tranxene), divalproex semisodium, divalproex sodium (Depakote), ethosuximide (Zarontin), ethotoin (Peganone), felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), levetiracetam (Keppra), mephenytoin, mephobarbital (Mebaral), methsuximide (Celontin), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), phenobarbital (phenobarbitone; Luminal, Solfoton), phenytoin (diphenylhydantoin; Dilantin, Phenytek), piracetam (Nootropyl), primidone (Mysoline), sodium valproate (Depacon), topiramate (Topamax), trimethadione (Tridione), valproate semisodium, valproic acid (Depakene, Depakene Syrup), vigabatrin (Sabril), zonisamide (Zonegran).

Similar properties but evidence lacking for extrapolation: Acetazolamide (Diamox; Diamox Sequels).

Effect and Mechanism of Action

Phenytoin, phenobarbital, primidone, and carbamazepine increase metabolic breakdown of vitamin K by inducing hepatic microsomal oxidase enzymes. The implications of drug exposure and iatrogenic vitamin K deficiency may pose particularly significant risks during and after pregnancy.

Research

Numerous researchers and clinicians have proposed that vitamin K deficiency due to anticonvulsant medications might pose significant risks for pregnant women. Vitamin K deficiency during fetal development has been known to result in facial bone abnormalities, specifically maxillonasal hypoplasia, known as Binder syndrome.[45,46] An elevated serum osteocalcin level indicates that the anticonvulsant drugs, particularly phenytoin and phenobarbital, are interfering with vitamin K metabolism.[47] The reduced levels of vitamin K–dependent clotting factors also increase the risk of bleeding problems during delivery. Such in utero exposure also results in increased risk for newborns because vitamin K–dependent hemostatic factors are present in reduced quantities at birth. Vitamin K administration during pregnancy offers preventive and therapeutic benefits, with little or no risk, for the general obstetric population. Nevertheless, although cases of increased bleeding and congenital abnormalities have been documented, evidence from clinical trials is lacking to validate the hypothesis that coadministration is particularly necessary and efficacious as a standard practice for women taking phenytoin and other hepatic enzyme-inducing antiepileptic drugs (AEDs) while pregnant.

For more than 60 years, public policy has recommended the prophylactic administration of vitamin K (1 mg intramuscularly) to infants at birth. Such clinical practice emerged before awareness of adverse effects of anticonvulsant medications and was largely derived from manufacturer recommendations aimed at general prevention of early, deficiency-related bleeding rather than specific concerns about maternal anticonvulsant use. Research into the frequency and severity of this risk suggests that previous studies and clinical concerns have overestimated the probability of significantly increased risk of excessive bleeding in newborns exposed to maternal enzyme-inducing anticonvulsants in utero. In 1993, Cornelissen et al.[48] published their findings from a multicenter observational case-control study comparing the incidence of vitamin K deficiency in mother-infant pairs exposed to anticonvulsant drugs, with 25 pregnant women receiving anticonvulsant therapy and 25 pregnant controls. Maternal vitamin K_1 concentrations were lower in women with epilepsy than in controls, but PIVKA-II (protein induced by vitamin K absence of factor II) was rarely present. Even though mothers were rarely vitamin K deficient, the incidence of vitamin K deficiency still was increased in neonates exposed to anticonvulsant drugs prenatally. In a 2002 paper, Kaaja et al.[49] prospectively followed 662 pregnancies in women with epilepsy who used a variety of enzyme-inducing AEDs and compared outcomes with 1324 nonepileptic pregnancies as controls. None of the mothers received vitamin K_1 during pregnancy, but all infants received 1 mg vitamin K_1 intramuscularly at birth. An analysis of bleeding outcomes revealed that factors other than maternal enzyme-inducing AED use were more likely to be associated with increased risk for bleeding in the offspring. Nevertheless, the authors advised that antenatal administration of vitamin K to mothers undergoing drug therapy may still be appropriate in selected cases.

Some literature reviewers considering formulation of preventive health care policy have criticized the practice of IM administration of vitamin K throughout the last third of pregnancy to all women receiving anticonvulsants as not supported by the available evidence.[50] Beyond the issue of maternal medications, the broader debate on vitamin K delivery for newborns has shifted, with multiple concerns arising about potential risks of injection and emerging research supporting the efficacy and safety of oral prophylaxis. In this area, as with many other concerns regarding therapies for at-risk pregnant women, the ability to adequately assess obstetric interventions is hampered by the limited number of interventional studies that included long-term outcome assessment. More research is warranted into the clinically important question as to whether maternal vitamin K oral administration reduces anticonvulsant-associated birth defects.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Women taking enzyme-inductive anticonvulsant medications may benefit, as may their infants, from vitamin K coadministration during pregnancy to prevent neonatal bleeding disorders and congenital facial bone abnormalities.

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Evidence: Warfarin (Coumadin, Marevan, Warfilone). Extrapolated, based on similar properties: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar).

Effect and Mechanism of Action

Coumarins are vitamin K antagonists that produce their anticoagulant effect by interfering with the cyclic interconversion of vitamin K and its 2,3-epoxide (vitamin K epoxide). Vitamin K is primarily located in hepatic microsomes, where the vitamin K–dependent gamma-carboxylation as the final step in synthesis of prothrombin and factors VII, IX, and X occurs. Gamma-carboxylation is linked to vitamin K metabolism, specifically the cyclic interconversion of vitamin K and vitamin K epoxide. The primary site of action of warfarin and indandione anticoagulants appears to be an inhibition of the conversion of epoxide to vitamin K in this cycle. Warfarin's anticoagulant effect is based on the the drug being structurally a vitamin K "mimic" that binds to the vitamin K–dependent enzymes more avidly than does vitamin K, but does not allow the enzyme its active form, thus preventing gamma-carboxylation of coagulation factors II, VII, IX, and X; paradoxically, warfarin can exert a procoagulant response by interfering with proteins C and S. Without the gamma-carboxylation step, the factors lack adequate activity in the coagulation cascade. This vitamin K–epoxide cycle occurs in extrahepatic tissues such as kidney, spleen, and lung and is inhibited by warfarin. Thus, vitamin K epoxide is an intermediary metabolite of vitamin K that accumulates when it cannot be utilized, and thus is a marker of warfarin effect. There is a correlation between the inhibition of prothrombin synthesis and the regeneration of vitamin K from the epoxide by anticoagulants.

Gamma-carboxylation of glutamyl residues, facilitated by vitamin K, not only activates clotting factors but also activates

osteocalcin and other bone matrix proteins. By inhibiting this process, vitamin K antagonists such as warfarin impair bone metabolism and increase the risk of osteoporotic fractures.[51]

Research

The simple issue of whether or not vitamin K, alone or in plant materials, interacts with warfarin and similar anticoagulants appears inherent and formulaic, which it is to a major degree. However, the nuances and complexities of individual variations and competing therapeutic agendas reveal a wider range of hidden risks and clinical options than initially evident. Moreover, a review of the research literature indicates that a significant gap exists between the therapeutic guidelines and prevailing clinical practices regarding the use of vitamin K for treatment of warfarin-associated coagulopathy.

A long-term debate as to the safest and most effective form of vitamin K for stabilizing an excessively elevated INR has recently approached an evidence-based consensus.[52] A series of randomized controlled trials, particularly those by Crowther et al.[53,54] and Lubetsky et al.,[55] have determined that oral vitamin K (phytonadione) lowers the INR more rapidly than subcutaneous vitamin K. Moreover, in some compromised ill patients, subcutaneous absorption, due to shunting of blood away from the skin, may actually be even less effective. Oral delivery also carries a substantially reduced risk of adverse reactions. In particular, intravenous administration carries a risk of anaphylaxis, although this may be significantly reduced by infusing over 30 minutes.

Clinical surveys, including ongoing research by Libby and Garcia[56] at the University of New Mexico, have determined that despite published reports of its safety and efficacy and established clinical protocols, a substantial number of anticoagulation clinics underutilize oral phytonadione in treating patients taking warfarin whose INR values are above therapeutic levels. In a 2002 paper, 100 separate anticoagulation clinics in the southwestern United States were surveyed with respect to the implementation of the recommendations for phytonadione use from the ACCP Fifth Consensus Conference on Antithrombotic Therapy. Of 53 respondents, 13 (25%) indicated that their clinics never use oral phytonadione. Eighteen (34%) indicated that their clinics use subcutaneous phytonadione, despite the absence of a recommendation for this in the 1998 ACCP guidelines. Only 17 respondents (32%) provided all four answers consistent with the ACCP recommendations.[56] The reasons for and implications of this apparent pattern of practice warrant broader and more in-depth research, in addition to confirming whether the observed phenomenon is representative of other geographic regions.

Individual sensitivity to warfarin is not consistent or fixed and appears to be influenced by vitamin K status, drug protein binding, and warfarin metabolism, among other variables. Reduced dietary vitamin K_1 intake potentiates the effect of warfarin in sick patients treated with antibiotics and IV fluids without vitamin K coadministration and in states of fat malabsorption. Hepatic dysfunction potentiates the response to warfarin through impaired synthesis of coagulation factors. Hypermetabolic states produced by fever or hyperthyroidism increase warfarin responsiveness, probably by increasing the catabolism of vitamin K–dependent coagulation factors. Lubetsky et al.[57] followed 50 patients commencing warfarin and consuming their regular diets for 8 weeks and concluded that in 32% (16/50) of anticoagulated patients under usual dietary conditions, sensitivity to warfarin is decreased by vitamin K intake of 250 µg/day or greater. Similarly, Cushman et al.[58] investigated the association of vitamin K status with warfarin sensitivity among 40 orthopedic patients beginning perioperative algorithm-dosed warfarin and found that dietary and biochemical measures of vitamin K status were associated with early warfarin sensitivity.

As Iqbal, Linder, and others have discussed, the pharmacodynamics of warfarin are subject to significant genetic and environmental variability.[59–62] Research by O'Reilly, Aggeler, et al.,[64–66] as well as by Alving et al.,[67] found that hereditary resistance to warfarin occurs in rats as well as humans. Individuals with genetic warfarin resistance require doses five-fold to 20-fold higher than average to achieve an anticoagulant effect. This pharmacogenomic pattern of response is attributed to altered affinity of the receptor for warfarin because the plasma warfarin levels required to achieve an anticoagulant effect are increased. Furthermore, Scordo et al.[68] evaluated the influence of CYP2C9 and CYP2C19 genetic polymorphisms on warfarin maintenance dose and metabolic clearance in 93 Italian outpatients receiving long-term warfarin anticoagulant therapy. They concluded that "CYP2C9 genetic polymorphisms markedly influence warfarin dose requirements and metabolic clearance of the S-warfarin enantiomer, although non-genetic factors may also contribute to their large interindividual variability."

Overall, a greater clinical understanding of, and development of experience with, the dynamic equilibrium between vitamin K intake and anticoagulant medications, with a heightened appreciation for and responsiveness to individual variability, physiological dynamics, and evolving health status, will enable safer and more effective utilization of anticoagulant therapy and reduce unrealistic assumptions of static physiological states.[69–71] Sconce, Kamali, et al.[72,73] have published a series of papers proposing an appraisal of current vitamin K–dosing algorithms for the reversal of overanticoagulation with warfarin, providing evidence to support vitamin K administration to "improve stability of anticoagulation for patients with unexplained variability in response to warfarin," and emphasizing the "need for a more tailored dosing regimen." Such an evolution of clinical practice will enable greater flexibility and reveal opportunities for support of a broader criterion for health than simple disease management as defined by INR levels, including integrative therapeutic strategies incorporating more robust dietary options and appropriate therapeutic application of herbal preparations, aimed at enhancing healthy function, reducing cardiovascular risk, and reducing reliance on anticoagulants over time.

Clinical Implications and Adaptations

By design, warfarin and similar anticoagulant medications achieve their therapeutic effect by interfering with vitamin K function and metabolism. Conversely, vitamin K therapy can be employed to antidote excessive effects of such anticoagulant therapies. Within the clinical practice of integrative medicine, warfarin therapy presents significant challenges to the implementation of botanical and nutritional therapeutics, let alone maintaining a simple healthy diet rich in nutritive plant foods. However, through communication, collaboration, and coordination, seemingly contraindicated therapies can be used together through high levels of vigilance, close monitoring, and responsive management within a context of integrative care bringing together medical practitioners trained and experienced in nutritional therapeutics, herbal medicine, and conventional pharmacology. As Jaffer and Bragg[74] judiciously pointed out in a 2003 review of warfarin dosing and monitoring: "There is no evidence that consuming less vitamin K is

more beneficial in maintaining anticoagulation control than consuming more."

Although the actions of anticoagulant medications and supplements, herbs, or foods containing vitamin K may be antagonistic on a tactical level, achieving and maintaining stability of coagulation factors are more important than mere presence or intake levels. More fundamentally, the primary strategic goals of disease prevention and health optimization must always remain clear and central. Amid valid concerns for effective anticoagulant protection, many physicians who prescribe coumadin anticoagulation instruct their patients to avoid consuming anything high in vitamin K, a practice that deprives them of many health-promoting phytonutrients. Consequently, from whatever source of information, many patients have been misinformed or otherwise come to believe that substances rich in vitamin K should be avoided if they are taking warfarin. However, simply eliminating plant foods rich in vitamin K and prohibiting use of therapeutically beneficial herbal prescriptions will not necessarily guarantee normalized INR values or support long-term medical objectives. Foods, herbs, and nutritional supplements inherently contain variable amounts of vitamin K and need to be evaluated with a thorough dietary assessment; the phylloquinone content of a wide range of foodstuffs has been listed by Sadowski et al.[75] Green leafy vegetables, such as kale, Swiss chard, spinach, broccoli, and mustard and turnip greens, are the foods that contain the highest amount of vitamin K per serving and thus are most likely to cause fluctuations in the INR.[76] Furthermore, in warfarinized patients any sudden reduction in intake of vitamin K from any of these sources is contraindicated because it may induce increased anticoagulation and increase bleeding risk through enhanced unopposed action of the medication.

Ultimately, the fundamental clinical management concern is maintaining a dynamic balance between vitamin K intake and warfarin, as represented in the INR; as such, however, the INR itself is secondary, if not irrelevant, to clinical outcomes and patient health, whether the patient reaches a therapeutic INR with 3 mg of warfarin, or 5, or 10, or even 20 mg. Warfarin itself is inexpensive and, unlike many pharmacological agents of its therapeutic potency, has no inherent toxicity or dose-related adverse effects, apart from its effects on vitamin K–related functions. Maintaining fairly constant vitamin K levels from both endogenous and exogenous sources is the key to stable anticoagulation with vitamin K antagonist anticoagulants. Thus, therapeutic agents containing vitamin K, whose actions are desirable for other reasons, are not necessarily contraindicated and can be used in the presence of anticoagulant medications if the individual has been stable during coadministration of such substances and anticoagulants, or if gradual, staged introduction of such agents is closely supervised and regularly monitored. Trust, communication, and education, along with systematic monitoring and flexible responses, are pivotal in the safe and effective management of vitamin K intake and INR stability within the context of a healthy diet and therapeutic use of herbal and nutritional therapies.

Management of a proper equilibrium between vitamin K intake and warfarin levels can be a challenging balancing act for both health care providers and patients, given the clinical importance of effective anticoagulant therapy and warfarin's narrow therapeutic index. Excessive vitamin K consumption can promote increased production of the vitamin K clotting factors, decreasing the anticoagulant response to warfarin. On the other hand, decreased vitamin K consumption can increase the anticoagulant response to warfarin. Normally it is sufficient to inform individuals taking warfarin to maintain a moderate and consistent level of vitamin K in their diet, to avoid binge eating of vitamin K–rich foods, and to report any significant changes in diet, supplement, or herbal intake to their anticoagulant management team. During the course of coadministration of vitamin K–rich herbs (or foods) and warfarin, the anticoagulant dose will need to be titrated, based on recognition that the effects of a dose adjustment on a given day will be seen in the INR 2 days later. In general, it would be reasonable to monitor the PT and INR more frequently when any dietary change, herbal therapy, or drug therapy is added or withdrawn from the regimen of a patient treated with an oral anticoagulant. Evidence from randomized controlled trials continues to support the use of less-intense warfarin treatment for many indications. For most patients, within an INR range of 2.0 to 3.0, the lower level generally is safer and equally effective. Whenever possible, it can be beneficial for patients undergoing warfarin therapy to have a home monitor so that they can monitor their INR daily during such transitional processes. However, the increasing availability of oral, direct thrombin inhibitors, such as Exanta, may soon reduce the risk of drug interactions and the need to restrict vitamin K intake, as well as provide a sufficiently predictable effect that high levels of monitoring become unnecessary.

Exercise is important in the elderly population and in individuals with cardiovascular disease. Clinical care needs to emphasize measures to counter the adverse effects of warfarin and other vitamin K antagonists on normal bone metabolism and subsequent elevation in the risk of osteoporotic fractures. Thus, particularly when prescribing anticoagulants to elderly individuals or others at high risk of falling, health care providers are advised to instruct patients to wear stable shoes, exercise regularly, maintain adequate intake of calcium and vitamin D, employ walking aids, and discontinue unnecessary and potentially complicating medications.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Acetylsalicylic Acid (Aspirin) and Salicylates

Acetylsalicylic Acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab).

Related salicylates: Choline salicylate, magnesium salicylate, salsalate, diflunisal, sodium salicylate, sodium thiosalicylate.

The combination of vitamin K sources and aspirin or salicylates represents a possible bimodal interaction and as such could be beneficial or self-defeating, depending on intention, coordination, and implementation. Long-term use of aspirin is supported by a broad base of evidence for reducing

cardiovascular risk but carries numerous adverse effects, including the possibility that it may increase the need for vitamin K. Aspirin and nonsteroidal anti-inflammatory drugs can produce gastric erosions that increase the risk of upper gastrointestinal bleeding. The resultant risk of clinically important bleeding is heightened when high doses of aspirin are taken in combination with high-intensity warfarin therapy (INR, 3.0-4.5). Conversely, vitamin K provides significant potential benefit in prevention of cardiovascular disease, but concern has been raised that increased intake may interfere with blood-thinning function of prophylactic aspirin. The mechanisms of such effect are uncertain and problematic because there is no well-known interaction between platelet function and vitamin K. Such concern may derive from a common misconception that because coumadin "thins blood," vitamin K in large amounts "thickens it" or creates a procoagulable state. Further research is warranted, and ultimately either a choice of therapeutic strategies may be required or protocols for innovative integrative options may prove effective in clinical trials.

Olestra

Olestra (Olean)

Olestra, the fat substitute composed of hexa-, hepta- and octa-esters of sucrose, may reduce the absorption of vitamin K and contribute to a deficiency.[77] Compensatory vitamin K supplementation may be advisable, espically on at-risk populations.

Orlistat

Orlistat (alli, Xenical)

Orlistat could theoretically reduce the absorption of vitamin K and other fat-soluble nutrients. Evidence of a significant depletion pattern is lacking. In a clinical trial involving 17 obese African-American and Caucasian adolescents receiving orlistat, 120 mg three times daily, McDuffie et al.[78] observed several significant nutrient depletion patterns, despite coadministration of a daily multivitamin containing vitamin A (5000 IU), vitamin D (400 IU), vitamin E (300 IU), and vitamin K (25 µg). However, during 3 to 6 months of orlistat treatment, the decrease in serum levels of vitamins K was not significant.[78]

NUTRIENT-NUTRIENT INTERACTIONS

Vitamin C

In 1952, Merkel[79] found that coadministration of menadione bisulfite and ascorbate provided complete relief of symptoms within 3 days in 64 of 70 consecutive cases of nausea and vomiting of pregnancy.

Vitamin K_2 combined with IV ascorbate has shown recent promise as an oxidative therapy for cancer. Similar preliminary studies have involved the use of vitamin K_3 in conjunction with IV ascorbate.[80-84] Vitamin K_3 is a more active free-radical generator than is K_2.

Vitamin E

Vitamin E in high doses may interfere with the absorption and utilization of vitamin K. In two independent, randomized clinical trials, Booth et al.[85] investigated the effect of 12 weeks of supplementation with RRR-alpha-tocopherol (1000 IU/day) on vitamin K status, as represented by several biochemical indicators, in 38 men and women with rheumatoid arthritis (study A) and in 32 healthy men (study B), none of whom were taking oral anticoagulants. Plasma phylloquinone concentrations and the percentage of undercarboxylated osteocalcin did not change significantly in response to the vitamin E. However, the degree of mean PIVKA-II (under-gamma-carboxylation of prothrombin; proteins induced by vitamin K absence–factor II), increased from 1.7 to 11.9 ng/mL in study A and from 1.8 to 5.3 ng/mL in study B after the 12 weeks of vitamin E supplementation. This pattern of potential interaction could play a role in cases of enhanced anticoagulant effect in response to high-dose vitamin E intake reported among patients taking oral anticoagulants.

Refer to the Warfarin section of the Vitamin E monograph for further discussion of these issues.

The 85 citations for this monograph, as well as additional reference literature, are located under Vitamin K on the CD at the back of the book.

Boron

Nutrient Name: Boron
Synonyms: Boron chelates—boron asportate, boron citrate, and boron glycinate; sodium borate.
Elemental Symbol: B.
Related Substance: Borax, boric acid.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Hormone replacement therapy (HRT) Estrogens/progestins X/⊕X/⊕⊕	Increased boron intake may contribute to elevated levels of estradiol (and testosterone). Coadministration of boron and estrogen enhancement therapies could provide synergistic benefit toward preventing bone demineralization, limiting bone loss, and treating osteoporosis. Concomitant use of exogenous female hormones and supplemental boron could theoretically increase risk of adverse effects of excess estrogen; however, available evidence suggests no association between high boron intake and elevated risk of breast cancer. Evidence from human research is limited. Well-designed long-term clinical trials are warranted.	Encourage increased dietary intake of boron-rich vegetables, fruits, and nuts as safe and efficacious, especially in conjunction with exercise and supplementation with calcium and vitamin D. Monitor when coadministration with supplemental boron indicated.

NUTRIENT DESCRIPTION

Chemistry and Form

Boron, the fifth chemical element, is a nonmetallic mineral present in the human body in trace amounts. In nature, boron is most prevalent as *borax*, which is a mixture of boron, sodium, and oxygen.

Physiology and Function

Boron is involved in the metabolic functions of many key nutrients, including calcium, copper, magnesium, phosphorus, potassium, and vitamin D. Although essential for plants, controversy remains unresolved as to whether boron is an essential nutrient for humans. Knowledge is incomplete as to the mechanism of absorption from the gastrointestinal tract, but it is known that dietary boron is rapidly absorbed. Boron is distributed throughout the body tissues, with the highest concentrations found in bones, dental enamel, spleen, and thyroid gland. Boron is primarily excreted in the urine, with bile, sweat, and breath serving as secondary routes of elimination.

The available streams of research have yet to coalesce into a comprehensive understanding of this nutrient's functions and relationships. Conventional research usually focuses on boron's particularly strong affinity for bone and joint tissue, where it influences composition, structure, and strength. However, a broader interpretation of the body of scientific evidence from animal and human studies indicates that boron acts as an essential ally of other substances in fine-tuning many human physiological interactions. Thus, boron exerts much of its influence by playing an integrative role in the areas of bone metabolism, joint health, mental acuity, wound healing, and proper functioning of the endocrine system.[1] Boron plays a major role in cell membrane functions, where it affects response to hormones (e.g., estrogen, vitamin D) that are involved in bone turnover and through its influence on transmembrane signaling or transmembrane movement of regulatory ions (e.g., calcium, magnesium). Boron participates in many aspects of the regulation of metabolism. For example, it lowers blood glucose levels in vitamin D deficiency states through its interaction with compounds having hydroxyl groups; it exhibits estrogen-mimetic activity; it appears to participate in regulating the respiratory burst of neutrophils; and it affects the activity of certain enzymes. Boron also plays an important but as-yet not fully elucidated role in cognitive and psychomotor functions.

The relationship between boron and calcium appears to be especially important, with increased boron levels associated with increased absorption of calcium, magnesium, and phosphorus and reduced urinary excretion of minerals, notably calcium. Boron facilitates metabolism of magnesium, copper, and potassium. It facilitates hydroxylation reactions to participate in the activation of vitamin D and to affect human steroid hormone levels and synthesis of estrogens and testosterone. Thus, increased boron intake may enhance both calcium absorption and serum levels of endogenous estradiol and testosterone. These multiple actions suggest that boron plays a key role in calcium and magnesium homeostasis, promotes bone mineralization, and mitigates bone loss, thus reducing the risk of osteoporosis. However, as with most nutrients, this effect is most significant in individuals with inadequate dietary intake of relevant minerals, with deficient magnesium intake being critical to variability in the activity of boron.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Consistent but limited evidence suggests that supplemental boron may be beneficial in supporting bone health and treating skeletal degeneration. In particular, preliminary evidence indicates that boron exerts beneficial effects on calcium metabolism and bone demineralization in postmenopausal women by reducing calcium loss (through excretion in the urine).[2,3] Findings from a double-blind, placebo-controlled pilot study involving 20 subjects with osteoarthritis demonstrated a significant favorable response to supplementation with 6 mg boron per day; 50% of subjects receiving the nutrient improved, compared with only 10% receiving placebo.[4] However, strong evidence is lacking from clinical trials to confirm boron's efficacy in preventing or treating osteoarthritis. Emerging epidemiological data and experimental research support the use of boron in prevention and treatment of prostate cancer.[1,5,6]

Some commentators have voiced the recommendation that food sources may be safer than supplements and therefore preferable. Nevertheless, health care professionals trained and experienced in nutritional therapies generally administer boron within the context of a comprehensive strategy including

calcium, vitamin D, magnesium, and trace minerals such as zinc, copper, and manganese. Principles of judicious clinical management suggest that laboratory assessment of boron levels to elicit deficiency status may be valuable.

Historical/Ethnomedicine Precedent

Boron has not been used historically as an isolated nutrient.

Possible Uses

Osteoarthritis, osteoporosis, prostate cancer, rheumatoid arthritis.

Deficiency Symptoms

Consensus is lacking on specific signs and symptoms of boron deficiency. However, observed effects of boron depletion include increased urinary loss of calcium and magnesium and increased rate of bone demineralization. Epidemiological evidence from geographic areas with low soil boron reveals an inverse relationship between the dietary intake of boron and the incidence of arthritis. In areas of the world where daily boron intakes usually are 1.0 mg or less, the estimated incidence of arthritis ranges from 20% to 70%, whereas in areas of the world where boron intakes are usually 3 to 10 mg, the estimated incidence of arthritis ranges from 0% to 10%. Therefore, patients living in such areas should be especially informed regarding this factor, and the same approach applies to other elements, significantly influenced by locale, such as selenium and vitamin D.

Dietary Sources

Raisins, prunes, dates, almonds, hazelnuts, and peanuts are the richest sources of boron. Significant amounts are available in most leafy vegetables, noncitrus fruits, and legumes, as well as beer, wine, and cider. However, the actual amounts of boron in plant sources will vary widely, depending on boron levels in the soil in which the food is grown. Meat, fish, and poultry provide minimal amounts of boron.

Dosage Forms Available

Capsule, liquid, tablet.

Source Materials for Nutrient Preparations

Sodium borate is the simple sodium salt of boric acid. Chelates are produced by reacting boron compounds with various organic and amino acids.

Dosage Range

Adult

Dietary: No dietary or nutritional requirement for boron has been established. Average adult boron intake in the United States has been estimated at 1 mg per day.[7] Rainey and Nyquist[8] confirmed this in a six-nation comparison of dietary boron conducted during the 1990s for the World Health Organization. They found that U.S. adults consumed, on average, slightly more than 1 mg daily, approximately 7% to 10% less than average boron intake levels of individuals in Britain and Egypt and 32% to 41% less than Germans, Kenyans, and Mexicans. Individuals who eat healthy amounts of fruits and vegetables, nuts, and legumes will generally have a boron intake in the range of 2 to 6 mg per day.[9]

Supplemental/Maintenance: The optimal dose of boron for proper physiological function and prevention of osteoporosis appears to be 3 to 6 mg per day.

Pharmacological/Therapeutic: Pharmacological doses used in clinical studies range from less than 1 mg up to 12 mg per day. Administration of 3 mg three times daily constitutes a typical therapeutic dose in the treatment of arthritis. A trial period of 2 to 4 months is usually indicated. Individuals being treated for rheumatoid arthritis will generally report symptom amelioration within 4 weeks of beginning boron supplementation.[10]

Toxic: The potential lethal dose for adults is estimated at 15 to 20 g per day[11]; 150 mg per liter of water represents a toxic concentration of boron.

Pediatric (<18 Years)

Dietary: No minimal dietary requirement established specifically for infants and children.

Supplemental/Maintenance: Not currently recommended for children.

Pharmacological/Therapeutic: Reports based on clinical observations indicate that children with juvenile arthritis (Still's disease) may improve in 2 to 3 weeks with administration of 6 to 9 mg boron daily.[10]

Toxic: No toxic dosage level established specifically for infants and children.

Laboratory Values

Deoxypyridinoline (D-ppd), and to a lesser degree pyridinium (Pyd), can provide a noninvasive evaluation of the biochemical markers of bone loss and assessment of bone resorption, which may be affected by multiple factors, including boron status.

Blood levels and hair analysis may also provide useful data in establishing boron status.

SAFETY PROFILE

Overview

Boron is generally considered relatively nontoxic for most individuals at usual supplemental doses, which are approximately equivalent to typical dietary intake levels. Adverse effects such as nausea and vomiting are only associated with doses 50 times the upper level of the recommended range.

Nutrient Adverse Effects

General Adverse Effects

Accidental acute exposure to high levels of boron (e.g., oral doses > 100 mg/day) can cause disturbances in appetite and digestion, nausea, vomiting, abdominal pain, diarrhea, dermatitis, convulsions, fatigue, and other symptoms; fatality is rare but has been reported.[12] The most frequently cited case involved a reported suicide where boric acid was ingested.[13]

Chronic exposures may be responsible for some toxic symptomatology. However, the daily dosage levels of 1 to 3 mg provided by most supplements containing boron have not been linked with toxicity in most reports. Areas with dietary boron intake of up to 41 mg/day have not produced associated patterns of adverse medical or health outcomes.

Adverse Effects Among Specific Populations

In one clinical trial, some menopausal women reported aggravations of hot flashes and night sweats with supplemental boron intake; others experienced amelioration of such symptoms.[14]

Pregnancy and Nursing

Qualified reports of adverse effects during pregnancy or nursing are lacking. However, the lack of clinical data from human trials or reports does not provide adequate evidence to confirm safety of boron during pregnancy and breastfeeding.

Infants and Children

Children exposed to boron-containing dusting powders and lotions, particularly containing borax or boric acid, constitute a high proportion of reports of toxicity. Irritation is common when such substances are applied to broken skin and mucous membranes. External boron-related preparations are generally best avoided.

Contraindications

Prudence suggests that supplemental boron be avoided during pregnancy because of potential effects on estrogen metabolism.

Precautions and Warnings

Newnham[10] has cautioned that individuals being treated for rheumatoid arthritis may experience an aggravation of symptoms (Herxheimer response) during the initial 1 to 3 weeks.

The increase in estrogen associated with elevated boron intake indicated by some preliminary research could theoretically increase the risk of several cancers. Nevertheless, no epidemiological evidence has confirmed an increased risk of cancer in areas of the world where dietary boron intake is high. Out of caution, some physicians have recommended that supplemental boron intake be limited to a maximum of 1 mg/day. Boron intake through regular consumption of fruits, vegetables, nuts, and legumes will generally exceed 1 mg/day and can provide a risk-free method for enhancing boron levels. Menopausal women experiencing increased hot flashes or night sweats might consider discontinuation of supplemental boron to determine whether the severity of their symptoms is reduced.

INTERACTIONS REVIEW

Strategic Considerations

The effects of boron on calcium metabolism and steroid hormone activity form the basis for the known and other potential therapeutic activity and related interactions. In particular, the probable interaction between boron and estrogen (as well as testosterone) may exemplify a bimodal interaction pattern. Boron's direct role in bone health and various effects on calcium, other minerals, and vitamin D provide its primary value (and common use) in preventing and treating osteoporosis and osteoarthritis.

Boron's potential ability to enhance estrogen (and possibly testosterone) could be therapeutically efficacious in supporting bone and joint health and preventing bone loss. However, concern has been raised as to potential risk of excessive estrogen response, especially in the context of hormone replacement therapy (HRT), which has already been associated with increased risk of breast and uterine cancer, as well as increased risk of dementia and thrombosis. Although long-term use of estrogen and progestin in combination does appear to lower a woman's overall risk for colon tumors, researchers say HRT users who do develop colon cancer are less likely to have it detected at an early stage, when it is most treatable. The coadministration of boron and estrogen support therapies could provide a valuable strategic synergy in the preventing bone loss and treating osteoporosis. Clinicians working to enhance the effects of estrogen are advised to monitor any changes in hormone status related to coadministration of boron. Conversely, restriction of boron intake could conceivably play a supportive role in therapeutic strategies aimed at limiting or reducing estrogen levels, such as in the prevention or treatment of estrogen-sensitive breast cancer. Boron supplementation might also prove useful in situations of hormone blockade and chemotherapy-induced osteoporosis, common in treatment of breast and prostate cancer, although careful clinical trials would be necessary to ensure that any increase in hormone levels induced by boron would be adequately offset by boron's apparent chemoprevention properties.

Evidence from in vitro, animal, and human studies indicates that boron can inhibit enzymes such as serine proteases, notably prostate-specific antigen (PSA). In a prostate cancer mouse model employing the LNCaP human prostate cancer cell line, boric acid has been found to decrease PSA by 87%, reduce tumor size, and lower tumor expression of insulin-like growth factor-1 (IGF-1), a tumor trophic factor.[15-18] As previously noted, dietary boron intake is strongly associated with reduced risk of prostate cancer.[6,8,19] Strum[1] has cited boron's known ability to inhibit cyclooxygenase (COX) and lipoxygenase (LOX), key enzymes mediating the inflammatory cascade, and noted: "Such anti-inflammatory capabilities of boron are clearly pertinent to its anti-cancer effect, because the reduction of COX II and LOX enzymes leads to a decrease in prostaglandin E_2 (PGE_2) and other unfavorable eicosanoids such as leukotrienes."

No reports or studies documenting drug-induced depletion of boron were accessible for review.

NUTRIENT-DRUG INTERACTIONS

Hormone Replacement Therapy (HRT): Estrogen-Containing and Synthetic Estrogen and Progesterone Analog Medications

HRT, estrogens: Chlorotrianisene (Tace); conjugated equine estrogens (Premarin); conjugated synthetic estrogens (Cenestin); dienestrol (Ortho Dienestrol); esterified estrogens (Estratab, Menest, Neo-Estrone); estradiol, topical/transdermal/ring (Alora Transdermal, Climara Transdermal, Estrace, Estradot, Estring FemPatch, Vivelle-Dot, Vivelle Transdermal); estradiol cypionate (Dep-Gynogen, Depo-Estradiol, Depogen, Dura-Estrin, Estra-D, Estro-Cyp, Estroject-LA, Estronol-LA); estradiol hemihydrate (Estreva, Vagifem); estradiol valerate (Delestrogen, Estra-L 40, Gynogen L.A. 20, Progynova, Valergen 20); estrone (Aquest, Estragyn 5, Estro-A, Estrone '5', Kestrone-5); estropipate (Ogen, Ortho-Est); ethinyl estradiol (Estinyl, Gynodiol, Lynoral).

HRT, estrogen/progestin combinations: Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); conjugated equine estrogens and norgestrel (Prempak-C); estradiol and dydrogesterone (Femoston); estradiol and norethindrone, patch (CombiPatch); estradiol and norethindrone/norethisterone, oral (Activella, Climagest, Climesse, FemHRT, Trisequens); estradiol valerate and cyproterone acetate (Climens); estradiol valerate and norgestrel (Progyluton); estradiol and norgestimate (Ortho-Prefest).

HRT, estrogen/testosterone combinations: Esterified estrogens and methyltestosterone (Estratest, Estratest HS).

Effect and Mechanism of Action

Boron may elevate estradiol and testosterone levels, especially in those with low dietary intake of boron and magnesium. The probable beneficial influence of boron in limiting calcium loss and supporting bone mineralization may be amplified by enhancement of steroid hormone status.

Research

Several small studies have shown an association between boron and increased estrogen levels, both in menopausal women not on estrogen replacement therapy (ERT) and healthy men and, more markedly, in women on ERT.

For many years a research team led by Nielsen, Hunt, and Penland in North Dakota has conducted numerous studies investigating boron, its activities, and therapeutic implications. In a 1987 clinical trial,[3] they observed marked changes in several indices of mineral metabolism in seven women consuming a low-magnesium diet and five women consuming a diet adequate in magnesium after administering a nutritional dose of boron (3 mg/day) for 48 days to these 12 women, age 48 to 82, not on ERT. Before the study, all subjects had consumed a conventional diet supplying about 0.25 mg boron daily for 119 days, that is, a diet essentially devoid of fruits and vegetables. Women receiving the boron demonstrated marked reductions in urinary excretion of calcium and magnesium and increased levels of plasma ionized calcium, especially in subjects receiving low dietary magnesium intake. Boron supplementation depressed the urinary excretion of phosphorus by the low-magnesium, but not by the adequate-magnesium, women. These researchers also reported marked elevations in serum concentrations of 17β-estradiol (the most potent of the naturally produced estrogens) and testosterone in response to the boron supplementation; again, the elevation was more pronounced in subjects on a low-magnesium diet. These findings "suggest that supplementation of a low-boron diet with an amount of boron commonly found in diets high in fruits and vegetables induces changes in postmenopausal women consistent with the prevention of calcium loss and bone demineralization."[3] Subsequently, Nielsen and Penland[14] reported elevated estrogen in several perimenopausal women administered 2.5 mg boron per day as well as other changes in boron metabolism and indices associated with macromineral metabolism, hormonal status, and immune function.

In a single-blind, placebo-controlled, crossover trial involving 18 healthy men, Naghii and Samman[20] reported that administration of boron at 10 mg/day for 4 weeks was associated with significantly increased plasma estradiol levels and a trend toward increased testosterone levels. These authors commented that the nutrient-induced elevation of endogenous estrogen suggests a protective role for boron in atherosclerosis.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The limited body of available evidence reveals a clear and emergent pattern indicating that health care professionals should encourage increased boron intake in individuals for whom elevated estrogen (and testosterone) levels will be beneficial, especially for preventing demineralization, limiting bone loss, and treating osteoporosis. Boron supplementation is especially important in postmenopausal women consuming a low-boron diet to prevent bone demineralization and osteoporosis; the importance of encouraging a varied diet rich in vegetables, fruits, and nuts cannot be overemphasized for general wellness and bone health in particular. A synergistic combination of oral calcium, vitamin D, boron, and magnesium, within the context of an active lifestyle, could reasonably be considered as a core proactive intervention within integrative therapeutics for all individuals at high risk for osteoporosis, or a foundational treatment for diagnosed bone loss. Additionally, hormone supplementation or replacement regimens (conventional HRT, bio-identical estrogens/progesterone, isoflavones, herbal hormone precursors/modulators) may achieve similar effects, but conclusive evidence is lacking; further research through clinical trials is warranted. Well-designed studies, published in peer-reviewed journals, have confirmed the benefits of ipriflavone and its amelioration of bone loss.

Dietary sources may be preferable, but evidence is lacking for claims of a significant adverse effects or increased risks attributable to boron supplementation at usual dosage levels of 1 to 3 mg/day. The consensus for increased dietary intake of foods rich in boron, especially nuts and fruits, receives at least nominal attention in conventional care and is strongly emphasized in health care providers trained and experienced in nutritional, preventive, and integrative approaches to healthy aging and bone-protective strategies. Some authors in secondary and derivative literature have voiced questionable, but often strong, cautions against use of supplemental boron as potentially risky because of possible elevated hormone levels. Such a concern for nutrient-induced adverse effects is curious, if not overstated, given the rising tide of research on adverse effects and limited efficacy of conventional estrogen-based HRT and momentous shift in health policy away from indiscriminate long-term HRT prescribing. Increased risks of breast and uterine cancer, as well as thromboembolism and dementia, may be related to artificial estrogen administration (and poor liver conjugation), but it is unreasonable to attribute such risks to boron. In fact, epidemiological evidence indicates that high boron intake from dietary sources does not affect breast cancer rates. Furthermore, the strong and growing trend of evidence supporting boron's role in reducing risk of prostate cancer (and potentially reversing pathological changes) dissuades against unfounded cautions regarding potential elevations in testosterone levels. Emerging evidence that boron functions as both a COX and LOX inhibitor may be related to its apparent activity as a candidate chemoprevention agent for both breast and prostate cancer. Clearly, the body of specific and general evidence from both the scientific literature and clinical experience supports increased boron intake as part of a comprehensive strategy for bone health.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Benign Prostatic Hypertrophy and Prostate Cancer Treatments

See Strategic Considerations.

NUTRIENT-NUTRIENT INTERACTIONS

Calcium

Boron exerts a favorable influence on calcium absorption, function, and excretion. In a 1987 clinical trial, Nielsen, Hunt, et al.[3] observed marked changes in several indices of mineral metabolism in seven women on a low-magnesium diet and five women on a diet adequate in magnesium, after a nutritional dose of boron (3 mg/day) for 48 days to these 12 women, age 48 to 82, not on ERT. Before the study, all subjects had consumed a conventional diet supplying about 0.25 mg boron daily for 119 days (i.e., a diet essentially devoid of fruits and vegetables). Women receiving the boron demonstrated marked reductions in urinary excretion of calcium and magnesium and increased levels of plasma ionized calcium, especially those receiving low dietary magnesium intake. Subsequent research by Nielsen et al.[21] indicated that 3 mg/day boron supplementation in men over age 45 and postmenopausal women on a low-magnesium diet contributed to several beneficial effects, including increased concentration of plasma ionized and total calcium, as well as reduced serum calcitonin concentration and urinary excretion of calcium. Later research by Nielsen[22] demonstrated that a low-boron diet elevated urinary calcium excretion.

Copper

Boron appears to increase serum levels of both copper and copper-dependent enzymes in humans. In a small trial involving five men over age 45, four postmenopausal women, and five postmenopausal women on estrogen therapy who had been fed a diet low in boron for 63 days, Nielsen et al.[21] demonstrated that boron (3 mg/day) administration resulted in higher erythrocyte superoxide dismutase (SOD), serum enzymatic ceruloplasmin, and plasma copper. Nielsen[22] confirmed these findings in a subsequent trial where the same variables were higher during boron repletion than while subjects were fed a diet low in boron. Higher SOD levels may be a mechanism of action for boron's improvement in degenerative joint disease. Some practitioners report using SOD in patients with outstanding results; SOD levels can be measured. The elevation in copper can be of concern because copper is a pro-angiogenesis element (in opposition to zinc).

Magnesium

Boron supports magnesium function and may assume some of its functions in states of magnesium deficiency. The interaction between boron and magnesium appears to be most significant when magnesium deprivation is severe enough to produce typical signs of deficiency.[23] Animal research by Hunt[24] indicated that a combined deficiency of boron and magnesium leads to detrimental alterations in the bones of animals. Introduction of additional boron elevated plasma magnesium concentrations and enhanced growth. Nielsen[2] and later Hunt et al.[25] found that boron's ability to reduce urinary loss of calcium disappeared when subjects were administered concomitant magnesium. Moseman[26] reported increased serum magnesium concentrations in female subjects after administration of supplemental boron. Meacham et al.[27] compared boron and magnesium in relation to exercise in women and found higher serum magnesium concentrations in sedentary females whose diets are supplemented with boron than in female athletes supplemented with boron while maintaining an exercise regimen.

Methionine and Arginine

In a series of nine experiments lasting 6 to 10 weeks using rats deprived of boron, Nielsen et al.[28] found that the severity of magnesium deprivation and the methionine status of the rat strongly influence the extent and nature of the interaction between magnesium and boron, as well as the response to boron deprivation. The beneficial impact of boron administration was consistently observed when the diet contained marginal methionine and luxuriant arginine. Depressed growth and bone magnesium concentration, as well as elevated spleen/body weight and kidney/body weight ratios, were among the signs exhibited by rats fed a diet marginal in methionine and magnesium. The authors interpreted their findings as indicating that the severity of such symptoms was alleviated with boron administration.

Phosphorus

Administration of boron appears to lower serum phosphorus concentrations. These effects have been observed in rats and in female subjects, age 20 to 27.[26,28] Exercise may diminish these effects as a result of increased loss of or elevated metabolic demand for boron.[26] Urinary excretion of phosphorus may be reduced when boron is administered in the context of low magnesium status, although not under conditions of adequate magnesium intake.

S-Adenosyl-L-Methionine (SAMe)

Ongoing studies are focusing on the naturally occurring molecules for which boron has an affinity, including *S*-adenosyl-L-methionine (*S*-adenosylmethionine, SAMe). Well-designed studies, published in peer-reviewed journals, have confirmed the benefits of SAMe in the treatment of osteoarthritis. Thus, given research demonstrating that boron may have a positive effect on osteoarthritis by helping to preserve bone, it may be reasonable to use boron in concert with SAMe to relieve painful arthritic symptoms.[29]

Vitamin B_2 (Riboflavin)

High doses of boron may increase excretion of riboflavin. Pinto et al.[30] showed that boric acid ingestion can induce urinary losses of riboflavin. Therefore, supplementation with B complex may be advised in patients with high boron intakes.

Vitamin D (Calciferol)

Boron appears to play a significant role in converting vitamin D to its more active form, thus facilitating calcium absorption. This observation is clinically relevant because it supports the practice of using vitamin D_3 with boron, rather than calcitriol, and thereby avoiding the high costs of calcitriol.

After examining animal nutrition models, Hunt[31] concluded that that dietary boron alleviates perturbations in mineral metabolism characteristic of vitamin D_3 deficiency. Hunt et al.[32] found that dietary boron modifies the effects of vitamin D_3 nutrition on indices of energy substrate utilization and mineral metabolism in the chick. For example, chicks fed a diet containing insufficient vitamin D for 26 days exhibited decreased food consumption and plasma calcium concentrations, as well as increased plasma concentrations of glucose, β-hydroxybutyrate, triglycerides, triiodothyronine, cholesterol, and alkaline phosphatase activity. Plasma glucose and triglycerides returned to concentrations exhibited by chicks fed a diet adequate in vitamin D after administration of boron. Such findings support the coadministration of boron and vitamin D_3 in diabetes management. Likewise, boron elevated the

numbers of osteoclasts and alleviated malformation of the marrow sprouts of the proximal tibial epiphyseal plate in rachitic (vitamin D–deficient) chicks, thus correcting a distortion characteristic of vitamin D_3 deficiency.[24] In an experiment investigating the effects of dietary boron in rats fed a vitamin D–deficient diet, Dupre et al.[25] observed that introduction of boron into the diet resulted in higher apparent-balance values of calcium, magnesium, and phosphorus.

In a study involving male subjects over 45 years of age and postmenopausal women fed a low-magnesium and low-copper diet, Nielsen et al.[21] showed that administration of 3.25 mg of boron per day increased levels of plasma vitamin D_3.

The 33 citations for this monograph, as well as additional reference literature, are located under Boron on the CD at the back of the book.

Calcium

Nutrient Name: Calcium.
Synonyms: Calcium ascorbate, calcium aspartate, calcium carbonate, calcium citrate, calcium gluconate, calcium lactate.
Elemental Symbol: Ca.
Related Substance: Microcrystalline hydroxyapatite (MCHC)

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Aminoglycoside antibiotics ≈≈/☼	Nephrotoxic effects of aminoglycosides can increase calcium excretion. Calcium coadministration may be protective but may potentiate adverse effects, especially of gentamicin, although such nephrotoxic synergy has only been demonstrated with parenteral, not oral, calcium coadministration.	Coadminister with extended use; closely monitor renal function and serum calcium, magnesium, and potassium.
Amphotericin B ≈≈≈/☼	Toxicity of amphotericin B associated with increased intracellular calcium concentration. This drug can deplete and disrupt calcium and other minerals. Well documented but not well understood.	Monitor electrolytes and coadminister minerals as indicated. Consider using less toxic liposomal formulation instead.
Antacids, aluminum- and magnesium-containing XXX/≈≈≈	Aluminum-based antacids may reduce calcium absorption and complex with phosphates to deplete calcium. Calcium citrate may increase aluminum absorption.	Avoid calcium citrate during therapy. Minimize use of aluminum-based antacids.
Anticonvulsant medications ≈≈≈/◈/☼	Antiepileptic drugs, particularly phenytoin and phenobarbital, can decrease calcium absorption, accelerate vitamin D metabolism in liver (CYP450 induction), and may reduce serum levels of 25(OH) vitamin D. Thus, anticonvulsants impair mineralization, leading to increased risk of bone loss, osteoporosis, and fractures. Mechanisms well established; clinical implications variable.	Coadminister calcium and vitamin D. Monitor serum 25(OH)D and bone status. Promote sunlight exposure and weight-bearing exercise.
Atenolol Beta-1-adrenoceptor antagonists ◈◈/◈	Simultaneous intake may inhibit absorption and bioavailability of both agents, which over time may increase drug half-life and may cause accumulation.	Separate intake by 2 hours. Monitor blood pressure and heart rate as indices of beta-blocker levels.
Bisphosphonates ⊕⊕⊕/◈◈/◈	Synergistic interaction. Vitamin D assists calcium absorption, and both enable bisphosphonates in maintaining bone mineralization, including with HRT.	Coadminister calcium and vitamin D. Promote appropriate sunlight exposure and weight-bearing exercise.
Calcitonin ⊕⊕	Calcium intake may enhance bone-sparing effect of calcitonin in prevention or treatment of osteoporosis. Pharmacologically reasonable; emerging evidence.	Coadminister calcium (and vitamin D if needed).
Calcium acetate XXX	Possible adverse effect from concomitant administration due to additive effect. Generally accepted; direct evidence lacking.	Avoid concomitant calcium. Monitor for hypercalcemia with calcium acetate.
Cholestyramine, colestipol Bile acid sequestrants ≈≈≈/◈	Bile acid sequestrants can impair calcium absorption by binding calcium and by reducing absorption of vitamin D and fat-soluble nutrients as a result of decreasing lipid digestion and absorption. Risk of deficiency and sequelae with extended use.	Supplement calcium and vitamin D. Promote sunlight exposure and exercise.
Corticosteroids, oral ≈≈≈/◈/☼	Oral corticosteroids reduce calcium absorption and may increase excretion while decreasing vitamin D availability and lowering serum levels. Increased risk of bone loss, osteoporosis, and fractures with long-term oral steroid use.	Supplement additional calcium and monitor bone and 25(OH)D status with steroid use > 1 month. Promote sunlight exposure and exercise.
EDTA ≈≈/XX	EDTA binds to calcium; thereby increasing calcium excretion and increasing risk of hypocalcemia or negative calcium balance.	Assess levels of calcium and other affected nutrients before treatment. Coadminister minerals.
Estrogens/progestins Oral contraceptives (OCs) Hormone replacement therapy (HRT) ⊕⊕⊕/☼	Synergistic interaction, especially with osteoporosis. Calcium can protect bone mineral density (BMD) during attainment of maximal peak bone mass in adolescence and early adulthood (with which OCs can interfere) and minimize later bone loss. Vitamin D assists calcium absorption, and both enable estrogen to inhibit osteoclastic activity and bone resorption and maintain bone mineralization. Progestins may counter benefit.	Coadminister with calcium and vitamin D (separate intake), possibly bisphosphonates. Monitor bone, 25(OH)D and HDL. Promote sunlight, nutrient-rich diet, and weight-bearing exercise.
Fluoroquinolone/ quinolone antibiotics ◈◈/≈≈	Chelation between this class of antibiotics and calcium likely to impair absorption of both, as well as other minerals. Calcium depletion and effects of bone loss plausible with extended use but not established or probable.	Discontinue calcium or separate intake during short-term therapy. Mineral supplementation may be appropriate with extended therapy; intake separated by several hours.
Gastric acid—suppressive medications Cimetidine, Histamine (H_2) antagonists Omeprazole, Proton pump inhibitors ≈≈≈	Cimetidine can decrease calcium absorption and transport through effects on vitamin D hydroxylase and vitamin D and impairment of gastric acid environment. Omeprazole can decrease absorption by reducing gastric acid production and increasing gastric pH. Possible deficiency with extended use.	Supplement with calcium other than carbonate; take separate from meals. Monitor bone density and 25(OH)D with chronic use, especially postmenopausal women.
Heparin, unfractionated ◈≈≈/≈≈/◈	Heparin therapy is associated with bone loss. Heparin may also inhibit formation of 1,25-dihydroxyvitamin D by kidneys and thereby reduce calcium absorption. Significant risk of bone loss with extended heparin use and nutrient depletion. Limited evidence supporting protective effect of supplemental calcium (or vitamin D).	Coadminister calcium and vitamin D, possibly as hydroxyapatite, where indicated. Monitor bone and $1,25(OH)_2$ status with heparin use > 1 month.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Isoniazid (INH) ≈≈/◇	Isoniazid can lower levels of both calcium and activated vitamin D levels; inhibit hepatic mixed-function oxidase activity, hepatic 25-hydroxylase and renal 1α-hydroxylase and reduce corresponding vitamin D metabolites. Drug-induced vitamin D deficiency can produce hypocalcemia and elevate parathyroid hormone (PTH). Nutrient support unlikely to interfere with therapeutic activity of medication.	Coadminister calcium and vitamin D when INH used for > 1 month. Promote sunlight exposure. Monitor 25(OH)D and bone status.
Levothyroxine Thyroid hormones ◇◇/≈≈≈/◇	Chelation between thyroid medications and calcium impairs absorption of both, particularly with calcium carbonate. Thyroid hormones increase urinary calcium excretion. Calcium depletion and effects of bone loss plausible with extended use, but not established or probable; risk greater in women with history of hyperthyroidism or thyrotoxicosis. Strong evidence for binding but evidence lacking for benefit from calcium coadministration.	Comorbid conditions may require both agents. Separate thyroid (morning) and calcium (bedtime). Monitor BMD with long-term use.
Metformin Biguanides ≈≈≈/◇≈≈/☼	Biguanides, especially metformin, reduce B_{12} absorption and lower serum B_{12} and holotranscobalamin by depressing intrinsic factor secretion and interfering with B_{12}/intrinsic factor uptake through calcium-dependent ileal membrane antagonism. Possible decrease of folate and increase of homocysteine.	Supplement B_{12}, folic acid, and calcium. Monitor folate and cobalamin status.
Sulfamethoxazole Sulfonamide antibiotics ≈≈≈	Sulfonamide can impair calcium absorption, as well as that of magnesium and vitamin B_{12}. Low probability of clinically significant effects on calcium balance with short-term therapy. Calcium depletion and effects of bone loss plausible with extended use, but not established or probable.	Intake separated by several hours. Additional calcium supplementation may be appropriate with extended therapy.
Tetracycline antibiotics ◇◇/≈≈≈/◇	Chelation between calcium and tetracycline antibiotics likely to impair absorption of both to clinically significant degree. Calcium intake, even small amounts, can significantly impair antimicrobial activity. Tetracycline also increases urinary calcium excretion. Calcium depletion and effects on calcium-dependent tissues (e.g., bones, teeth) probable, and adverse effect on bone formation or density possible with extended use; increased concern with adolescents and elderly.	Discontinue calcium (including dairy foods), or separate intake during short-term therapy. Calcium supplementation usually appropriate with extended therapy, with intake separated by several hours.
Thiazide diuretics ✗✗/◇◇/⊕✗/⊕⊕	Thiazide diuretics increase calcium retention by decreasing urinary calcium excretion; decreased calcium absorption, suppressed PTH secretion, and inhibited vitamin D synthesis also appear to be effects of thiazides. Concomitant use with supplemental calcium theoretically increases risk of hypercalcemia; low probability of occurrence. Not a substitute for increased calcium intake; benefits of increased calcium retention cease when thiazide discontinued. Evidence incomplete.	Monitor calcium levels before initiating and periodically during concomitant use of calcium or vitamin D.
Verapamil Calcium channel blockers ✗✗/⊕✗/⊕⊕/≈≈	Verapamil may decrease endogenous vitamin D synthesis and induce target-organ PTH resistance. Calcium administration can be used to reduce adverse effects of calcium channel blockers; concurrent use of verapamil and intravenous calcium salts, in particular, can be therapeutically efficacious (e.g., control cardiac tachyarrhythmias) yet avoid hypotensive effect of calcium channel blocker. Conversely, increased calcium availability may oppose verapamil's activity as calcium antagonist, particularly when antihypertensive effect desired. Theoretically, excess calcium (or vitamin D) might contribute to hypercalcemia, which in turn might precipitate cardiac arrhythmia in patients on verapamil. Minimal evidence; rare occurrence but potentially severe.	Concurrent supplementation with calcium (and vitamin D) may be appropriate, but only under close supervision. Consider bone support needs.

EDTA, Ethylenediaminetetraacetic acid; *HDL*, high-density lipoprotein; *INH*, international normalized ratio.

NUTRIENT DESCRIPTION

Chemistry and Forms

Calcium ascorbate, calcium aspartate, calcium carbonate, calcium citrate, calcium citrate-malate (citramate), calcium gluconate, calcium lactate, calcium malate; microcrystalline hydroxyapatite (MCHC); calcium acetate; bonemeal, dolomite; calcium glycerophosphate, dicalcium phosphate, tricalcium phosphate; calcium phosphate (dairy calcium).

Physiology and Function

Calcium is the most abundant mineral in the human body, with 99% of it stored in bone and teeth. The remaining 1% of body calcium is found in the blood, extracellular fluid (ECF), and soft tissue. Normal physiological functioning requires that homeostatic systems in the intestines, bones, and kidneys, in concert with parathyroid hormone (PTH), calcitonin, vitamin D, and other hormones, maintain calcium levels in the blood and ECF within very narrow concentration parameters. Calcium absorption in the intestines will increase if blood levels decrease. Likewise, renal excretion can be reduced to maintain calcium levels. Ultimately, however, bone will be demineralized to maintain normal calcium parameters when intake is inadequate to sustain the physiological functions of calcium in bone and teeth, cellular structure, endocrine function, cell signaling, nerve transmission, blood clotting, blood pressure regulation, enzyme activation, and muscle contraction.

A dynamic and complex system involving calcium absorption, bone formation and resorption, renal reabsorption and

excretion, and hormonal regulatory networks enables rapid and tight control of blood calcium levels. Calcium is absorbed in the duodenum, jejunum, and ileum by an active saturable process that involves vitamin D and PTH. Calcium exhibits threshold absorption that depends on the interplay among dietary intake, blood and tissue levels, gender, life stage and activity level, gastric pH, hormonal milieu, vitamin D receptor genotype, and numerous other factors. Except for dietary intake, the major factors influencing the efficiency of absorption are physiological requirements and age. Thus, in childhood, adolescence, pregnancy, and lactation, the intestinal calcium absorption process becomes more efficient; conversely, it is impaired in the elderly, especially with decreased physical activity levels. Calcium bioavailability depends to some extent on vitamin D status. PTH stimulates the conversion of vitamin D to calcitriol, its active form, primarily in the kidneys and to some degree in other tissues. Calcitriol increases the absorption of calcium from the small intestine. At high intakes, some calcium is absorbed by passive diffusion (independent of vitamin D). Some absorption can also occur from the colon. Together with PTH, calcitriol activates osteoclasts to stimulate the release of calcium from bone and increases renal tubular reabsorption to reduce excretion of calcium through the urine. On reaching normal blood calcium levels, the parathyroid glands suspend PTH secretion, and the kidneys resume excretion of any excess calcium through the urine. Unabsorbed and endogenously secreted calcium is eliminated through the feces. Perspiration and breast milk also act as pathways of calcium excretion.

Calcium ions play a major role in the structural aspect of physiology. Hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$, a crystalline calcium carbonate/calcium phosphate compound, is the form of calcium primarily responsible for providing rigidity and strength to bones and teeth. Positive calcium balance is maintained during development and growth until peak bone density is attained, becomes neutral as adults mature, and is often negative in the elderly. Thus, bone density increases during the first three decades of life until it reaches its peak at about age 30. Thereafter, bone density stabilizes before moving into a pattern of gradual decline. Both men and women experience diminishing bone density as they age, but women experience more significant and rapid decline after menopause. Calcium and vitamin D insufficiency during adolescence and young adulthood can significantly curtail peak bone density, dramatically increasing the risk of osteoporosis in later life.

Calcium facilitates muscle activity by aiding transport across cell membranes. Muscles require calcium for proper contractile function. Without calcium, the muscles tend to stay in the contracted state. The cell membranes of skeletal muscle cells, nerve cells, and other electrically excitable cells are characterized by voltage-dependent calcium channels that enable rapid changes in calcium concentrations. For example, the nerve impulse entering a muscle fiber to stimulate contraction triggers calcium channels in the cell membrane to allow influx of calcium ions into the muscle cell. Calcium ions are released from intracellular storage vesicles as these calcium ions bind to troponin-*c* and set in motion the process of muscle contraction. Meanwhile, the binding of calcium to calmodulin activates glycogenolysis in the muscle to provide energy necessary for contraction.

As with striated muscle throughout the body, the heart requires calcium for proper contractility. A sudden decrease of ionized serum calcium can cause tetany, leading to cardiac or respiratory failure. Likewise, calcium plays a role in mediating the constriction and relaxation of blood vessels (vasoconstriction and vasodilation).

An array of proteins and enzymes require calcium as a cofactor for optimal activity and stabilization. For example, activation of seven of the clotting factors in the coagulation cascade requires the binding of calcium ions. Ionized calcium initiates the formation of blood clotting by stimulating the release of thromboplastin from blood platelets. It is also a cofactor in the conversion of prothrombin to thrombin, which converts fibrinogen to fibrin, and then aids in its polymerization to form a stable clot.

Calcium also regulates membrane stabilization. Certain cells (e.g., mast cells) tend to rupture when calcium ions are depleted. In addition, neurotransmitters at synaptic junctions are regulated by calcium. This may have effects on such conditions such as anxiety, insomnia, and other stress-related conditions.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Calcium plays many essential roles in human physiology, but it primarily receives attention in conventional medicine and patient inquiries in regard to bone health, aging, and osteoporosis. Nevertheless, calcium has a proven influence on risk for numerous pathological patterns and needs to be emphasized as a critical nutrient beginning at an early age. Calcium intake during childhood and especially during adolescence is perhaps the most significant factor in establishing healthy bone mass and preventing osteoporosis, although exercise is an equally and possibly more important factor.[1] Calcium too often becomes a concern as aging progresses and the threat of bone loss is looming or initial signs of osteoporosis are already present. Unfortunately, when awareness of need develops during middle age and menopause, it is usually too late for optimal calcium nutriture to function in a preventive mode.[2-5]

Evidence for beneficial effects of calcium supplementation on *bone mineral density* (BMD), most often studied in women before and after menopause, is mixed, with slowing the pace of further bone loss becoming the realistic clinical objective in most cases. Inherently, the significance of variables such as calcium intake, beverage habits, hormone history and status, and lifestyle factors (e.g., exercise, smoking) all complicate the issues and confound analysis of the available data.[6,7] Thus, although the current dietary and calcium supplementation recommendations are almost always advisable, they are unlikely to reverse the process of age-related bone loss without a comprehensive and strategic approach utilizing multidisciplinary interventions.

The collective evidence indicates that a diet rich in calcium from plant sources deserves much more attention, and that the common advice to consume dairy products may be less well founded than generally presumed. Furthermore, the tendency of adolescents to displace milk consumption with carbonated beverages during the most critical life stage for peak bone mass development tips the calcium balance in a deleterious direction, given the calcium-depleting action of phosphates found in many soft drinks, as well as drawing on the skeletal mineral reserve to buffer the acid load imposed by habitual consumption of large quantities of these acidified carbonated drinks. Experts in clinical nutrition generally recommend that individuals obtain as much calcium as possible from a diverse, nutrient-rich, and balanced diet. Foods that provide calcium usually contain other important nutrients, such as magnesium, manganese, copper, zinc, vitamin D, and vitamin K, that work synergistically with calcium. Moreover, intake of calcium levels

above 800 mg (elemental calcium) per day is probably unnecessary for maintaining calcium metabolism in most individuals, provided that vitamin D status is adequate, except for pregnancy and lactation.[8]

Calcium absorption is variable, both between different individuals and also with differing forms of calcium. Individuals of Asian and African heritage absorb calcium more efficiently than do Caucasians.[9] Different forms of calcium are absorbed at different rates. The pH of the stomach often influences how well certain calcium salts will be absorbed. The more water-soluble forms of calcium, such as citrate and citrate-malate, tend to have a greater absorption rate, especially in people who are deficient in hydrochloric acid, such as the elderly, or those taking gastric acid–suppressive medications. Furthermore, vitamin D intake and blood levels, as well as vitamin D receptor genotype, can significantly influence calcium bioavailability and absorption.[10] Bran and high-fiber cereals are high in phytates, which can reduce calcium absorption, although this is probably not clinically significant for most individuals over time at typical levels of consumption.

Historical/Ethnomedicine Precedent

Dark-green leafy vegetables, hard cheeses, sesame seeds, seaweed, and other components of traditional indigenous diets have long been emphasized for their contributions to health and longevity. Dairy consumption has been part of some cultural traditions for long periods, although controversy continues as to whether it is always in association with a genetic capacity to digest, assimilate, and metabolize dairy foods.

Possible Uses

Amenorrhea (bone loss prevention), anxiety, arthritis, blood clotting, blood pressure regulation, cardiovascular disease, celiac disease (related deficiency), colon cancer (risk reduction), colorectal cancer, depression, dysmenorrhea, gestational hypertension, gingivitis, hyperactivity, hypercholesterolemia, hypertension, hypertriglyceridemia, hypoparathyroidism, insomnia, insulin resistance syndrome, kidney stones (calcium oxalate stone prevention), migraine, multiple sclerosis, obesity, osteoporosis, periodontal disease, postpartum support, preeclampsia (related deficiency), pregnancy support, premenstrual syndrome, restless legs syndrome, rickets, stroke.

Related Therapeutic Applications

Calcium carbonate is used as an antacid. Calcium carbonate and calcium acetate can be used as phosphate binders in renal failure. Calcium chloride and calcium gluconate are used intravenously in treating severe hypocalcemia.

Deficiency Symptoms

Simple calcium deficiency is not a recognized clinical disorder, and standard laboratory tests, except bone scans during middle age, offer little useful data to evaluate calcium status for individuals with suboptimal or even moderately compromised intake, development, and peak bone mass. Long-term calcium deficiency contributes to growth deficiency in children; poor tooth development is also characteristic. A lack of calcium in adults may cause osteoporosis and osteomalacia and result in bone deformities, bone pain, and fractures. Other symptoms related to a deficiency are tetany or other muscle spasms. These usually occur in the legs. However, they may also occur in the blood vessels and may lead to hypertension. Other, typically more advanced, symptoms of calcium deficiency include nausea and vomiting, headaches, candidiasis, dry skin and nails, alopecia, neuromuscular irritability, muscular spasms and contracture, tetany, arrhythmias, convulsions, anxiety, depression, insomnia, and psychosis.

Calcium insufficiency, depletion, and deficiency can result from a wide range of factors and are usually gradual in onset and difficult to reverse once established. Decreased intake, inadequate weight-bearing exercise, blood loss (both internal and external), menorrhagia, lead toxicity, and malabsorption all can lead to calcium deficiency. Deficiencies in vitamin D and magnesium can contribute to calcium deficiency. A growing body of evidence indicates that vitamin D status is compromised in a large portion of the population, particularly adolescents and the elderly, because of inadequate intake and lack of exposure to sufficient sunlight. Magnesium deficiency results in decreased responsiveness of osteoclasts to PTH. Compromised calcium status during development will prevent the attainment of optimal peak bone mass. Once that opportune phase is passed, inadequate calcium intake may contribute to accelerated bone loss and ultimately the development of osteoporosis.

However, increased absorption of dietary calcium, rather than an increased intake or decreased excretion of calcium, appears to be the most influential factor in rapid acquisition of bone mineral during pubertal growth. Thus, the effects of dietary factors on calcium absorption efficiency are modulated by calcium status, genetic factors (e.g., specific vitamin D receptor gene polymorphisms), and height and body size.[10-14] Furthermore, malabsorption conditions (e.g., Crohn's disease, celiac disease, surgical intestinal resection), prolonged bed rest, excessive menstrual blood loss, and a range of pathologies and medical interventions can also contribute to calcium depletion and potential deficiency.

Dietary Sources

Hard cheese, almonds, sesame seeds, filberts, and dark-green leafy vegetables are considered *high* in calcium, with greater than 200 mg/100 g food.

Milk, yogurt, sunflower seeds, Brazil nuts, broccoli, parsley, and watercress are considered *medium* in calcium, with greater than 100 mg/100 g food.

Average dietary intakes of calcium in the United States (U.S.) are well below the adequate intake (AI) recommendation for every age and gender group, especially in females and most significantly in children 9 to 17 years old. Furthermore, surveys consistently find that up to 85% of postmenopausal women do not consume adequate calcium every day, and on average consume about 500 mg less than the U.S. recommended dietary allowance (RDA). "Despite increasing public awareness and patient education about the importance of calcium [intake], this analysis shows the average daily calcium intake has not improved since the landmark Study of Osteoporotic Fractures (SOF)," conducted from 1986 to 1988, which found that postmenopausal women's average daily calcium intake was 714 mg daily.[15]

The issue of calcium bioavailability from milk and dairy products remains a contentious issue, more often dominated by cultural habit and marketing than by nutritional science. In a systematic review of 58 clinical, longitudinal, retrospective, and cross-sectional studies on the relationship between milk, dairy products, or calcium intake and bone mineralization or fracture risk in children and young adults (1-25 years old), Lanou et al.[16]

concluded: "Scant evidence supports nutrition guidelines focused specifically on increasing milk or other dairy product intake for promoting child and adolescent bone mineralization." Furthermore, large segments of the populations may not have the genetic background for digestion and assimilation of cow's milk, or any milk, past infancy, with resulting food intolerances, lactase deficiency, and food allergies being increasingly recognized for their clinical import.

Consumption of cola-containing drinks, but not other carbonated beverages, appears to be associated with lower BMD in older women.[17]

Nutrient Preparations Available

The issue of which form of supplemental calcium is "best" belies the broader issues of biochemical individuality in general and gastrointestinal function in particular. Organically bound calcium, such as aspartate, citrate, gluconate, or chelated forms, generally demonstrates higher bioavailability than inorganic calcium, such as carbonate, phosphate, or sulfate; such bioavailability is particularly significant in individuals with insufficient gastric acid or poor bowel constitution and in the elderly. ***Calcium carbonate*** is the least expensive and most well-known form of calcium, but it frequently causes constipation and bloating and may not be well absorbed by individuals with reduced levels of stomach acid.[18] When calcium carbonate is taken with orange or other citrus juice, a significant amount of calcium citrate is formed, and absorption appears to be enhanced, even in subjects with low gastric acidity. Calcium citrate and heated oyster shell–seaweed calcium may be better absorbed than calcium carbonate; other evidence indicates no significant difference in bioavailability. Studies have shown a normally functioning bowel can ionize calcium carbonate and the lumen can absorb it well; after it is absorbed, it can be converted to aspartate, then an orotate, so that it can be absorbed into the cells.[19-21]

Calcium lactate and calcium gluconate are also more efficiently absorbed than calcium carbonate. Calcium citrate appears to be better tolerated in the elderly and by those with sensitive digestive systems and may offer superior efficacy in preventing the progression of osteoporosis. Calcium citrate-malate (citramate) is absorbed better and tolerated more consistently than calcium carbonate.[22] Many physicians and other health care professionals experienced in nutritional therapy have increasingly turned to calcium citramate as their preferred form of calcium. Some evidence suggests efficacy of microcrystalline hydroxyapatite (MCHC) in cases where osteoporosis is the greatest concern. This form of calcium is purported to have a special affinity for bone formation, but some have asserted that it may not be absorbed well.

Dosage Forms Available

Capsule, chewable tablet, functional foods (e.g., orange juice fortified with calcium citrate), liposomal spray, liquid, powder, tablet; injection (prescription only).

Source Materials for Nutrient Preparations

Oyster shells (calcium carbonate), dolomite, bonemeal (calcium hydroxyapatite); calcium ascorbate, calcium aspartate, calcium citrate, calcium citrate-malate, calcium gluconate, calcium glycerophosphate, calcium lactate, calcium malate, dicalcium phosphate, and tricalcium phosphate are calcium salts of the corresponding organic acid, produced by titrating the acid with calcium hydroxide or other basic form. Soluble forms of calcium phosphate along with other minerals present in milk have been extracted from milk and are being used to fortify other foodstuffs.

Most calcium supplements (85%) currently sold in the U.S. are made from calcium carbonate, which contains the greatest percentage of elemental calcium on a weight basis, but is also the least water-soluble calcium salt.

Note: Lead contamination has been observed in some forms of supplemental calcium, particularly dolomite, bonemeal, and oyster shell.[23-25] The U.S. federal limit for lead content is 7.5 micrograms (μg) per 1000 milligrams (mg) elemental calcium. Good manufacturing practice has established an industry standard of keeping the amount of lead in calcium supplements to less than 0.5 μg/1000 mg elemental calcium. A product survey published in 2000 reported measurable lead in 8 of 21 supplements, in amounts averaging 1 to 2 μg/1000 mg elemental calcium.[26] Calcium inhibits intestinal absorption of lead, and adequate calcium intake is protective against lead toxicity. Consequently, calcium deficiency could potentially present a greater risk of lead intake due to general lead exposure than associated with trace amounts in calcium supplements.

Dosage Range

No multivitamin/multimineral capsule or tablet contains 100% of the recommended daily dose of calcium because it would be too bulky and too large to swallow. For example, 1 g calcium carbonate contains 400 mg elemental calcium and 1 g calcium citrate contains 211 mg elemental calcium. Furthermore, because calcium exhibits an absorption threshold, absorption is maximized by limiting each dose to 500 mg elemental calcium.[27] Thus, supplemental calcium intake is most efficacious when the daily intake is divided into two or more doses, preferably with meals (and away from most medications). Concomitant vitamin D will enhance calcium absorption.

Adult

Dietary: In the United Kingdom, the average daily diet provides 961 mg for men and 764 mg for women.
Supplemental/Maintenance: 500 to 2500 mg per day.

For individuals age 19 to 50: 1000 mg/day (including diet)
For adults age 51 and older:
Women: 1500 mg/day (including diet)
Men: 1200 mg/day (including diet)
Pregnant and breastfeeding females under 19 years: 1300 mg/day (including diet)
Pregnant and breastfeeding females age 19 and older: 1000 mg/day (including diet)

Note: These recommendations do not incorporate research demonstrating that doses above 800 mg/day may be unnecessary with adequate vitamin D levels.

Pharmacological/Therapeutic: Calcium intake as high as 3000 mg/day, together with 10 to 50 μg/day vitamin D_3 (cholecalciferol), may be appropriate if plasma calcium and phosphate levels are stable and within normal range (e.g., in treatment of secondary hyperparathyroidism in uremia).[28]

Calcium deficits associated with vitamin D deficiency may warrant daily doses up to 6000 mg of calcium acetate or calcium carbonate.
Toxic: Total calcium intake, from combined dietary and supplemental sources, should not exceed 2500 mg/day for long-term use. Large, acute doses normally exhibit no toxic effects.

The tolerable upper intake level (UL) established by the U.S. Food and Nutrition Board (FNB), Institute of Medicine, for vitamin C in adults (≥ 19 years) is 2500 mg/day.

Pediatric (<18 years)
Dietary:

Infants, birth to 6 months: 210 mg/day; breast-feeding optimal
Infants, 7 months to 1 year: 270 mg/day
Children, 1 to 3 years: 500 mg/day
Children, 4 to 8 years: 800 mg/day

Supplemental/Maintenance: A daily intake of 1300 mg total calcium (diet plus supplements) is generally considered necessary to promote the attainment of maximal peak bone mass in children and adolescents.
Pharmacological/Therapeutic: 500 to 2500 mg/day.
Toxic: UL for calcium:

Infants, 0 to 12 months: Not established; dietary source only recommended
Children, 1 to 13 years: 2500 mg
Adolescents, 14 to 18 years: 2500 mg

Laboratory Values

Serum Calcium

Normal levels: 2.2 to 2.6 mmol/L (8.4-10.2 mg/dL).

Serum calcium levels are maintained within tight parameters under most circumstances and do not provide accurate or sensitive markers for calcium status. Low blood calcium level usually implies abnormal parathyroid function and/or vitamin D deficiency, or low serum albumin. Elevated blood calcium levels are more likely to occur in response to higher absorption during calcium deficiency than with true excess. More often, elevated blood calcium occurs from hyperparathyroid states, vitamin D excess (usually in lymphoma, or sarcoid, or other granulomatous diseases where pathological tissues convert 25-OH vitamin D to calcitriol autonomously), or hypercalcemia of malignancy, which is usually caused by tumor-produced hormones that have PTH-like activity. Milk-alkali syndrome, as discussed later, is of historical interest only as a cause of hypercalcemia.

Ionized (Unbound) Serum Calcium

Normal levels: 1.17 to 1.29 mmol/L.

Low levels may indicate negative calcium balance.

Urinary Calcium

Normal levels:

Women: Approximately 150 to 250 mg/day
Men: Approximately 200 to 300 mg/day

SAFETY PROFILE

Overview

Calcium is generally considered safe at usual doses. Even in large doses, calcium absorption is limited, blood and tissue levels are tightly regulated, it is efficiently excreted, and toxicity rarely results. Some forms of calcium, notably calcium carbonate, may cause abdominal bloating, flatulence, and constipation in some individuals. Interference with absorption of other nutrients, particularly magnesium, iron, and zinc, as well as some medications, is the primary adverse effect associated with large doses of calcium. However, concern has been raised in recent years about excessively high levels of lead in some forms of calcium, particularly those derived from bonemeal, dolomite, and oyster shell.

Nutrient Adverse Effects

General Adverse Effects

Hypercalcemia has been reported in association with calcium supplements and antacids but has never been attributed to dietary (i.e., food) sources of calcium. Ingestion of extremely large amounts of calcium (5000 mg/day, or >2000 mg/day over long period) can produce a toxic response. However, excess calcium levels are more likely to result from pathological processes such as hyperparathyroidism, certain types of cancer, kidney failure, breakdown of bone, or excessive levels of vitamin D.

Mild hypercalcemia is usually asymptomatic, but higher levels (>12 mg/dL) often result in symptoms that include loss of appetite, nausea, vomiting, constipation, abdominal pain, dry mouth, thirst, and frequent urination. More severe hypercalcemia may result in renal toxicity, cardiac arrhythmias, confusion, delirium, coma, and if not treated, death.

Milk-alkali syndrome, resulting from concomitant consumption of large quantities of milk, calcium carbonate (antacid), and sodium bicarbonate (absorbable alkali), represents the most well-known form of hypercalcemia. This obsolete treatment for peptic ulcers often involved calcium supplement levels from 1.5 to 16.5 g/day for 2 days to 30 years.

Increased excretion of calcium by the kidneys (*hypercalciuria*) constitutes a more significant risk factor for nephrolithiasis than does high calcium intake per se. In fact, most evidence indicates that enriched dietary calcium is associated with a decreased risk of oxalate kidney stones (which represent 80% of renal stones), presumably due to binding of dietary oxalate in the gut, thus decreasing its absorption. However, one large prospective study found that women taking supplemental calcium (of unspecified form) had a 20% higher risk of developing kidney stones than those who did not. These researchers also observed that women consuming low-calcium diets were at greater risk for stones than those with higher calcium intakes, perhaps, as they speculated, because of reciprocal hyperoxaluria.[29] Nevertheless, a diet low in animal protein and sodium, but with normal calcium levels, is more effective in preventing recurrence of calcium oxalate kidney stones than a diet low in calcium.[30] The form of calcium may be the differentiating factor deserving further investigations. Some clinicians have reported that calcium citrate can be beneficial in preventing or reversing kidney stones and bone spurs, and that calcium carbonate is more frequently associated with pathological calcification processes. As noted, higher levels of calcium from food may complex with dietary oxalates in the intestines and reduce their absorption; likewise, taking calcium supplements separate from food will significantly reduce their beneficial effect of decreasing intestinal oxalate absorption.

Adverse Effects Among Specific Populations

Risks from calcium supplementation are significantly greater in individuals with hyperparathyroidism, certain types of cancer, kidney failure, or other conditions that interfere with normal calcium regulation.

Pregnancy and Nursing

Evidence of adverse effects in pregnancy resulting from calcium supplementation is lacking. Calcium supplementation is

generally advised during pregnancy and lactation and can reduce risk of preeclampsia.

Infants and Children

Some sources have suggested that calcium supplements should be used under medical supervision in young children because of a risk of bowel perforation. Nondairy foods rich in calcium are preferred, with human breast milk being the superior food source for infants. Liquid forms are available when supplementation is appropriate. Children may also do well with some chewable forms, although some products contain sugar, which is not recommended.

Contraindications

Calcium supplementation is contraindicated in some individuals with hyperparathyroidism, chronic renal impairment or kidney disease, sarcoidosis or other granulomatous diseases, cancer patients with a history of hypercalcemia, or patients with a history of idiopathic calcium stones (except the common calcium oxalate stones, in which calcium supplementation with meals may reduce the risk of stone formation by binding dietary oxalate).

Precautions and Warnings

Caution is generally appropriate in conditions associated with hypercalcuria and hypercalcemia. Soft tissue calcification may occur with hyperparathyroidism, hyperphosphatemia, magnesium deficiency, or vitamin D overdoses. Calcium supplements should be used with caution and with medical supervision in hypertensive individuals because blood pressure control may be altered. As previously suggested, judicious selection of the form of calcium used may reduce or even reverse the risk factors involved with supplementation in individuals with these conditions.

High calcium intake, primarily from milk and dairy products, may increase prostate cancer risk by lowering concentrations of 1,25-dihydroxyvitamin D_3 [$1,25(OH)_2D_3$], a hormone thought to protect against prostate cancer. The epidemiological evidence, however, is mixed. Other evidence indicates that calcium supplementation is not associated with increased risk of prostate cancer.[31-36] Nevertheless, calcium supplementation is sometimes considered as contraindicated in men diagnosed with prostate cancer. If calcium were found to have such an adverse effect, concomitant supplementation with vitamin D might provide a safe, simple, and effective counterpoint.

INTERACTIONS REVIEW

Strategic Considerations

The many interactions involving calcium reveal several consistent patterns. Nevertheless, most of the available clinical research has inadequate specificity, depth, complexity, and duration and cannot capture many of the nuances that will enable clinicians to navigate their diverse implications. Calcium and many medications can interfere with each other in ways that are easily avoided or that require tactical choices within a strategic approach. On occasion, the adverse effects on calcium-rich tissue can be swift and permanent (e.g., tetracycline, sometimes corticosteroids). More often, medications interfere with calcium function or cause steady depletion that will increase risks of adverse effects over time. Notably, physicians prescribing such agents over extended periods (e.g., anticonvulsants, opioids and oral glucocorticoids) usually do not advise or prescribe adequate countermeasures, whether calcium and vitamin D, bisphosphonates, or the combination, to address effectively the common occurrence of drug-induced decreases in BMD and increased risk of fracture.[37,38] Conversely, the risk of hypercalcemia/hypercalciuria from calcium intake through supplements or dietary sources is improbable outside of metabolic pathologies influencing the calcium and vitamin D regulatory systems. Overall, calcium tends to follow the patterns of other dense aspects of nature and physiology, which come on gradually, move slowly, and can be difficult to reverse once established.

Calcium and many medications complex or otherwise bind to each other, thus reducing absorption of both agents. During short courses of treatment, this interaction may reduce drug absorption and activity to a clinically significant degree. In contrast, any short-term interference with calcium assimilation will not interfere with the intended therapeutic action in a strategically important degree, given that most uses of calcium are long term, preventive, or cumulative. In most situations, simple temporal separation of intake is adequate to avoid such interference; when not sufficient, however, the calcium may need to be temporarily discontinued, usually with minimal or no impact on therapeutic intentions. Importantly, calcium-fortified foods, such as orange juice, are often not thought of as "calcium supplements" and can significantly interfere with absorption of pharmaceutical medications that bind to calcium, when taken with such beverages.

Significant and often severe limitations in the ability to reach conclusions about interactions involving "calcium" occur because of the various calcium salts potentially involved. Too often, an easy but potentially misleading tendency is to generalize from research that often is not clear, especially in secondary sources and derivative literature, and particularly in abstract form. An even greater interpretive error is to extrapolate from findings involving parenteral calcium to the use of oral calcium supplements; the two situations are physiologically vastly different, and almost never comparable. Calcium carbonate and calcium phosphate are best taken with meals to optimize absorption.[21] Other calcium salts can be taken without regard to food intake or meals; this may make them preferable for hypochlorhydric individuals and patients prescribed H_2 antagonists or other medications that reduce gastric acidity, particularly proton pump inhibitors (PPIs).

The literature is further complicated by the presence of research and case reports involving calcium salts as antacids, particularly when observations regarding such substances are extrapolated to calcium supplements. Except for differences in the substances themselves, gastric acidity, achlorhydria, and acid suppression are all complicating issues of significant import. Likewise, some studies and many commentators fail to distinguish between calcium intake from calcium supplements and that from dietary intake of milk and dairy products.

Multiple variables (e.g., individual biochemical variability, gender, life stage, diet, vitamin D status) that influence how "calcium" will be absorbed and function in any given individual need to be further evaluated before considering the medications and conditions being treated.

The inadequacies of standard knowledge and clinical practice regarding the prevalence and assessment of vitamin D deficiency emerging in recent years will increasingly reveal deep implications for calcium balance, bone health, and much more. Many agents that deplete calcium or otherwise interfere with its metabolism do so indirectly through their adverse effects on vitamin D status. Although direct effects on calcium

may also be present, the effects on vitamin D can significantly impair calcium absorption and activity. Conversely, elevated levels of vitamin D can cause an increased absorption of calcium.

Pervasive vitamin D deficiency status and underutilization of laboratory assessment for 25-hydroxyvitamin D [25(OH)D] levels influence and limit research design, interpretation, and clinical practice within conventional medicine. For example, in 2005, two randomized controlled trials of calcium carbonate and cholecalciferol (vitamin D_3) reported that administration for prevention of fractures in primary care produced widely publicized conclusions declaring that such nutrient supplementation provided no value in preventing fractures.[39,40] Such assertions were made despite disclosures that (1) vitamin D levels had been tested in only a small sample of the subjects in one of the studies; (2) vitamin D deficiency appeared to be common within the subject populations, as indicated by responses to vitamin D supplementation; (3) quality control of the supplements was very poor; (4) compliance was marginal and declined over time (e.g., 63%, or as low as 45%); and (5) the use of calcium carbonate in a population of older and often hypochlorhydric subjects would be considered suboptimal by many, if not most, experienced practitioners of nutritional therapeutics. Digestion of calcium carbonate relies on the integrity of gastric function and the bowel culture to produce the ionizing acids. Thus, gastrointestinal adverse effects, typical of calcium carbonate, were cited as a major factor in greater noncompliance with calcium intake.

In the study in which 1% of the subjects had their vitamin D levels actually measured, there was only a marginal increase after 1 year of supplementation with 800 IU of vitamin D per day (although when analyzed, some of the supplements contained as little as 372 IU, mean value, per tablet). Average 25(OH)D levels at beginning of the study (15 ng/mL) were in the range of severe deficiency, and after 1 year improved only to 24 ng/mL, still well below what many vitamin D researchers consider to be adequate levels (30–40 ng/mL).[41] Subsequently, in a trial involving 944 healthy Icelandic adults, Steingrimsdottir et al.[8] found that with 25(OH)D levels below 10 ng/mL, maintaining calcium intake above 800 mg/day appeared to normalize calcium metabolism, as determined by the PTH level, but in individuals with higher 25(OH)D levels, no benefit was observed from calcium intake above 800 mg/day. Clearly, further research on calcium and other minerals involved in bone metabolism need to take into account, and preferably optimize, vitamin D status.

Notably, in conventional practice, the main pharmacological intervention for the prevention of bone loss is antiresorptive drugs, such as bisphosphonates, for which almost every clinical trial has included coadministration of calcium or vitamin D. Moreover, the decontextualization and narrow focus of these studies highlight the shortcomings of standard research methodology and clinical practice to consider the broad factors of aging, lifestyle, activity level, drug depletions, and poor nutritional status characteristic of the populations in question, as well as the complex nature of bone health and its reliance on interdependencies of multiple nutrients and tissues, rather than using such a narrow focus on supplemental calcium and vitamin D. As public and practitioner attention on vitamin D grows, it may prove a pivotal issue in expanding perceptions and awareness, analysis, and intervention through a broad integrative model more accurately reflecting patient needs, with a scientific understanding of the breadth and complexity of the processes involved.

Ultimately, perhaps the most limiting aspects of the research findings generally available involve the questions asked, the assessment methods used, and the time frames considered. As noted in many sections, the markers of blood calcium levels and other short-term indices do not adequately address the issue of calcium depletion over time; the feedback systems of calcium homeostasis involve vitamin D synthesis and activation, calcium absorption, tubular reabsorption and urinary excretion, PTH production and secretion, and bone formation, catabolism, and resorption. Thus, as a drug interferes with calcium absorption and metabolism and induces a depletion pattern anywhere along the way, superficial parameters may remain within normal parameters, but the long-term state of bone density may be in steady decline. For this reason, it is often clinically useful to assess markers of bone breakdown, such as urinary pyridinium cross-links (pyridinium and deoxypyridinium), as a baseline, when starting a pharmaceutical intervention with the potential to impact calcium balance negatively. An increase in urinary markers of bone breakdown signifies the development of negative calcium balance, despite all other markers related to calcium appearing normal, because of intrinsic calcium homeostatic mechanisms. This can serve as an early warning sign and allow for nutritional interventions to correct negative calcium balance without waiting to find a decrease in bone density on a subsequent bone density scan.

NUTRIENT-DRUG INTERACTIONS

Aminoglycoside Antibiotics, Including Gentamicin and Neomycin

Evidence: Gentamicin (Garamycin), neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin).
Extrapolated, based on similar properties: Amikacin (Amikin), kanamycin (Kantrex), netilmicin (Netromycin), paromomycin (monomycin; Humatin), streptomycin, tobramycin (AKTob, Nebcin, TOBI, TOBI Solution, TobraDex, Tobrex).

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
2. Probable

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Gentamicin exhibits a significant risk of nephrotoxic effects and can cause increased urinary calcium loss. Concomitant administration of calcium may have a protective effect but may also potentiate gentamicin-induced nephrotoxicity. Neurotoxic effects are also well known.

Neomycin impairs calcium absorption when taken orally.

Research

Animal studies indicate that renal tubular damage caused by aminoglycosides, such as gentamicin, can lead to hypocalcemia combined with hypokalemia, hypomagnesemia, and alkalosis.[42–44] In a retrospective study, Schneider et al.[45] found that coronary artery bypass graft (CABG) patients who received both a bypass prime with a high calcium concentration (6.25 mmol/L) and gentamicin perioperatively had a higher incidence of renal failure compared with those who received only the prime, gentamicin alone, or neither.

Reports

A 12-year-old boy developed renal wasting of magnesium, calcium, and potassium, with secondary hypomagnesemia, hypocalcemia, and hypokalemia (without hyperaldosteronism), after treatment with 14,400 mg gentamicin over 4 months.[46] Other case reports involving gentamicin have described similar adverse effects on electrolytes, particularly hypomagnesemia.[47-49]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians administering extended courses of gentamicin or other aminoglycosides should monitor kidney function as well as plasma magnesium, calcium, and potassium levels during and after treatment. Magnesium levels in red blood cells (RBCs) can provide a more reliable picture of magnesium status than testing serum magnesium. Serum creatinine, blood urea nitrogen (BUN), and creatinine clearance should also be measured before initiating therapy and monitored throughout treatment. Nutritional support may be required to restore normal levels of calcium and other important minerals. Prolonged courses of gentamicin should be avoided if less nephrotoxic antibiotics are suitable. Oral neomycin in preparation for surgery is unlikely to produce clinically significant deficiencies.

Calcium coadministration in the range of 500 to 1000 mg per day may beneficial for individuals being treated with aminoglycosides for longer than 2 to 3 days. Slow-K and Micro-K are typical examples of the potassium suggested by most physicians. Patients can further enhance their potassium levels by eating several pieces of fresh fruit each day. However, increasing potassium intake by any means is usually contraindicated and often dangerous in patients with reduced kidney function. Coadministration of magnesium in the dosage range of 300 to 500 mg per day is usually appropriate but should be done in collaboration with a physician trained and experienced in nutritional therapies. Magnesium supplementation is risky in patients with renal insufficiency and is usually contraindicated in such cases. It is also important to note that magnesium is needed to maintain intracellular potassium due to magnesium dependence of the membrane Na^+, K^+-ATPase enzyme, as well as calcium, because parathyroid hormone (PTH) is a magnesium-requiring hormone. Intravenous (IV) magnesium replacement is preferred for correction of frank hypomagnesemia.

Amphotericin B

Amphotericin B (AMB; Fungizone).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

The ability of amphotericin B to increase intracellular calcium concentrations is associated with the toxicity of this antifungal agent. Calcium depletion is a generally accepted adverse effect of amphotericin B; sodium, potassium, and magnesium are similarly depleted. Hyperphosphatemia has also been observed. This medication exerts adverse effects on renal function, but details of possible metabolic pathways are not known.

Reports

Amphotericin B lipid complex (ABLC) is a liposomal formulation that is less nephrotoxic than conventional amphotericin B and can be given more safely to patients with preexisting renal impairment with no apparent loss of efficacy. Nevertheless, cases of severe hyperphosphatemia resulting from high-dose liposomal amphotericin have been reported.[50]

Nutritional Therapeutics, Clinical Concerns and Adaptations

Physicians administering amphotericin B are advised to monitor electrolyte status and consider supplementation with a multimineral formulation during extended treatment. Aberrations of serum electrolytes, including calcium, concomitant with amphotericin therapy may require parenteral management.

Antacids Containing Aluminum and Magnesium

Aluminum carbonate gel (Basajel), aluminum hydroxide (Alternagel, Amphojel), aluminum hydroxide and magnesium hydroxide (Advanced Formula Di-Gel Tablets, Co-Magaldrox, Di-Gel, Gelusil, Maalox, Maalox Plus, Mylanta, Wingel), aluminum hydroxide and magnesium trisilicate (Alenic Alka, Gaviscon Chewable); aluminum hydroxide, magnesium carbonate, alginic acid, and sodium bicarbonate (Gaviscon Extra Strength Tablets, Gaviscon Regular Strength Liquid, Gaviscon Extra Strength Liquid); aluminum hydroxide, magnesium hydroxide, calcium carbonate, and simethicone (Tempo Tablets); aluminum hydroxide, magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); magnesium hydroxide (Phillips' Milk of Magnesia MOM), magnesium trisilicate (Adcomag trisil, Foamicon).

Similar properties but evidence indicating no or reduced interaction effects: calcium-containing combination drugs: aluminum hydroxide, calcium carbonate, magnesium hydroxide, and simethicone (Tempo Tablets); calcium carbonate and magnesium hydroxide (Calcium Rich Rolaids); magnesium hydroxide and calcium carbonate (Calcium Rich Rolaids).

See also Gastric Acid–Suppressive Medications.

Interaction Type and Significance

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Aluminum-based antacids may reduce calcium absorption and can complex with phosphates to cause a depletion of calcium stores. Aluminum hydroxide causes increased loss of calcium through urine and stool.

Calcium citrate has been found to act similar to citrus juice in significantly increasing aluminum absorption from antacids.

Research

Concomitant intake of calcium citrate can significantly increase aluminum absorption from both dietary sources and aluminum-containing antacids.[51-54] Weberg et al.[55] examined the mineral-metabolic effects of a 4-week course of a conventional low-dose aluminum-magnesium antacid in 10 healthy volunteers, who were given one antacid tablet after the three main

meals and at bedtime (buffering capacity, 120 mmol/day). They observed significant changes from premedication state, including an increase in urinary excretion of magnesium, calcium, and aluminum; decrease in urinary excretion of phosphate; increase in maximal renal phosphate reabsorption; and increase in serum concentration of aluminum. All these parameters returned to normal levels within 3 to 4 days after cessation of antacids.[55] In a study involving eight male subjects, Coburn et al.[56] found that coadministration of 5 mL of aluminum hydroxide gel (2.4 g four times daily) and calcium citrate (950 mg four times daily) for 3 days "markedly enhances aluminum absorption from aluminum hydroxide" and increases urinary aluminum excretion. In a trial involving 30 healthy women, Nolan et al.[25] observed that calcium citrate (800 mg elemental calcium daily) significantly increased absorption of aluminum from dietary sources (i.e., with no additional exposure to aluminum in antacids) and resulted in significantly increased urinary aluminum excretion and plasma aluminum level. During monitoring, however, they noted no changes in urine or whole-blood lead levels. Further research is warranted to determine whether long-term use of calcium citrate contributes significantly to aluminum accumulation and toxicity and the relative role of antacids in such risk.

Antacids containing magnesium and aluminum can increase calcium elimination, particularly urinary and stool loss.[57]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing antacids containing aluminum (and magnesium) should advise patients to avoid calcium supplements, particularly calcium citrate, during the course of treatment; citrus juice is also contraindicated. In general, use of aluminum-based antacids should be discouraged given the mineral's inherent toxicity. The risks of an adverse reaction between calcium citrate and aluminum-containing compounds are especially high for individuals with kidney failure, particularly those on dialysis. Consider alternative approaches to antacid therapy using calcium or magnesium compounds without aluminum content.

Anticonvulsant Medications

Carbamazepine (Carbatrol, Tegretol), clonazepam (Klonopin), clorazepate (Tranxene), divalproex semisodium, divalproex sodium (Depakote), ethosuximide (Zarontin), ethotoin (Peganone), felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), levetiracetam (Keppra), mephenytoin, methsuximide (Celontin), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), phenobarbital (phenobarbitone; Luminal, Solfoton), phenytoin (Dilantin, Phenytek), piracetam (Nootropyl), primidone (Mysoline), sodium valproate (Depacon), topiramate (Topamax), trimethadione (Tridione), valproate semisodium, valproic acid (Depakene, Depakene Syrup), vigabatrin (Sabril), zonisamide (Zonegran).

Similar properties but evidence lacking for extrapolation: Acetazolamide (Diamox; Diamox Sequels).

Interaction Type and Significance

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
2. Probable

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Many anticonvulsants, including phenobarbital, cause reduced calcium absorption with long-term use.[58] Some anticonvulsants, such as phenytoin and phenobarbital, adversely affect calcium metabolism by reducing serum levels of calcidiol and thereby altering hepatic metabolism of vitamin D, at least in part by accelerating its metabolism and increasing the excretion of its metabolites.[59,60] Thus, hypocalcemia and subsequent bone loss during anticonvulsant therapy may be the result of vitamin D deficiency. Consequently, by multiple possible mechanisms, anticonvulsant medications may reduce serum calcium levels.

Research

Long-term therapy with phenytoin and other anticonvulsants can disturb vitamin D and calcium metabolism and result in osteomalacia. Both epilepsy and anticonvulsant medications are independent risk factors for low bone density, regardless of vitamin D levels. Long-term anticonvulsant treatment can cause excessive metabolism and deficiency of vitamin D and is believed to be associated with decreased bone mineral density (BMD) and bone loss.

In vitro research involving rat bone culture by Somerman et al.[61] found that phenytoin reduced 1,25-dihydroxycholecalciferol and inhibited vitamin D–mediated bone resorption even after phenytoin treatment was discontinued. Several studies have found that patients on long-term anticonvulsant therapy exhibit reduced serum concentrations of 25-hydroxycholecalciferol.[62,63] Both forms of vitamin D are necessary for calcium absorption.[6,64]

In a 1982 study involving 30 adult epileptic patients, Zerwekh et al.[65] reported decreased serum 24,25-dihydroxyvitamin D concentration during long-term anticonvulsant therapy (with phenytoin, phenobarbital, or carbamazepine), with phenobarbital-treated patients exhibiting a significant decrease in serum 25-OHD. They noted that various anticonvulsant agents appear to exert different effects on vitamin D metabolism.

After finding no pattern of low serum levels of vitamin D (25-OHD) or radiological evidence of osteomalacia or rickets in more than 400 individuals using anticonvulsants in Florida, Williams et al.[66] concluded that the climate provided adequate exposure to sunshine and thereby prevented the development of anticonvulsant-induced osteomalacia or rickets. "In contrast to reports from northern climates, we found minimal evidence of anticonvulsant-induced bone disease." Subsequently, in a controlled trial, Riancho et al.[67] studied 17 ambulatory epileptic children taking anticonvulsants for two seasons with high and low levels of solar radiation and observed that although serum 25-OHD concentrations were normal among medicated subjects during the summer, their levels were significantly lower than those of controls during the winter months.

In initiating a prospective 3-year study, Hunt et al.[68] found that of 144 children and young adults who required anticonvulsant therapy, 52 were found to have serum alkaline phosphatase (ALP) levels elevated more than two standard deviations (SDs) above normal, and half these showed signs of rickets or osteomalacia. After slow and gradual but varying rates of response to calcitriol, all patients showed significant lowering of serum ALP levels by 30 months of follow-up. In a later controlled study, Jekovec-Vrhovsek et al.[69] determined that bone strength improved (specifically, BMD increased) in 13 institutionalized children undergoing long-term anticonvulsant therapy who were supplemented for 9 months

with 0.25 μg daily 1,25-dihydroxycholecalciferol vitamin D, the activated form of vitamin D, and 500 mg daily calcium.

Telci et al.[70] compared bone turnover in 52 epileptic patients receiving chronic anticonvulsant therapy with 39 healthy volunteers as matched controls and found that the resorption phase of bone turnover is affected during chronic anticonvulsant therapy. Total serum ALP levels (a marker of bone formation) were significantly increased in patients from both genders compared with those of their controls. Among male epileptic patients, urinary deoxypyridinoline levels (a marker of bone resorption) were significantly increased while 25-OHD levels were significantly reduced compared with those of their controls.

Farhat et al.[71] compared the effects of various antiepileptic drugs (AEDs) on bone density in 71 adults and children anticonvulsant therapy for at least 6 months. More than half the adults and children/adolescents had low serum 25-OHD levels. Although this finding did not correlate with their BMD, the AEDs were strongly associated with decreased BMD in the adults, particularly at skeletal sites enriched in cortical bone. Furthermore, lower BMD was more consistently associated with enzyme-inducing agents (e.g., phenytoin, phenobarbital, carbamazepine, primidone) than with medications that did not induce enzymes (e.g., valproic acid, lamotrigine, clonazepam, gabapentin, topamirate, ethosuximide). These researchers concluded: "Generalised seizures, duration of epilepsy, and polypharmacy were significant determinants of bone mineral density."

In 2001, Valmadrid et al.[72] published a survey of practice patterns of neurologists. They found that only 41% of pediatric and 28% of adult neurologists performed routine evaluation of patients receiving AEDs for either bone or mineral disease. Further, among those physicians who detected bone disease through such diagnostic testing, 40% of pediatric and 37% of adult neurologists prescribed either calcium or vitamin D. However, only 9% of pediatric and 7% of adult neurologists prescribed prophylactic calcium or vitamin D for patients taking AED therapy.

Reports

Duus[73] reported a case of several severe fractures in a patient following epileptic seizures. The patient had epileptic osteomalacia and responded well to vitamin D treatment.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing anticonvulsant medications are advised to coadminister calcium (200-400 mg three times daily) and vitamin D (200-400 IU twice daily) if the course of treatment is expected to last more than 1 month. Pretreatment and posttreatment monitoring of serum 25-OHD and $1,25\text{-}OH_2D$ levels would also identify individuals at risk of treatment-induced and nutritional/sunlight-related deficiencies of vitamin D. With regard to supplementation, calcium needs to be taken at least 2 hours before or 4 hours after the medication to avoid interfering with drug absorption; calcium carbonate should be avoided in favor of another form less likely to impair drug activity. Individuals in growth phases (children and adolescents) are most vulnerable to depletion patterns and resultant bone loss and other potential adverse effects. Furthermore, many individuals with epilepsy, especially children, lead restricted lifestyles and are often institutionalized or under other forms of full-time care. Such individuals not only experience the effects of the pathophysiology on vitamin D metabolism, but also tend to have compromised nutritional status and restricted time outdoors in the sun, especially during winter months. Thus, sunlight represents an effective and low-risk method of supporting vitamin D status. Walking and other simple forms of weight-bearing exercise will also support bone health and increase the efficacy of nutrient enhancement through dietary and supplemental sources.

Concomitant calcium administration carries a low probability of adversely affecting the efficacy of anticonvulsant therapy. Further research is warranted to develop knowledge of this interaction pattern, factors influencing individual susceptibilities, and clinical options for appropriate therapeutic responses.

Atenolol and Related Beta-1-Adrenoceptor Antagonists (Beta-1-Adrenergic Blocking Agents)

Evidence: Atenolol (Tenormin), sotalol (Betapace, Betapace AF, Sorine).

Extrapolated, based on similar properties: Atenolol combination drugs: atenolol and chlorthalidone (Co-Tendione, Tenoretic); atenolol and nifedipine (Beta-Adalat, Tenif).

Similar properties but evidence lacking for extrapolation: Acebutolol (Sectral), betaxolol (Kerlone), bisoprolol (Zebeta), carteolol (Cartrol), esmolol (Brevibloc), labetalol (Normodyne, Trandate), metoprolol (Lopressor, Toprol XL); combination drug: metoprolol and hydrochlorothiazide (Lopressor HCT); nadolol (Corgard), nebivolol (Nebilet), oxprenolol (Trasicor), penbutolol (Levatol), pindolol (Visken), propranolol (Betachron, Inderal LA, Innopran XL, Inderal); combination drug: propranolol and bendrofluazide (Inderex); timolol (Blocadren).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **4. Plausible**

Evidence Base: **▽ Mixed**

Effect and Mechanism of Action

Simultaneous intake of atenolol or other beta blockers along with calcium salts may inhibit absorption and bioavailability of both substances and reduce plasma concentrations of the medication.[74] Long-term coadministration may increase the drug half-life and lead to accumulation.

Research

In a clinical trial involving five healthy subjects, Kahela et al.[75] observed that administration of sotalol with a calcium gluconate solution substantially reduces the absorption and bioavailability of sotalol. In a similar experiment involving six healthy subjects, Kirch et al.[76] found that oral administration of 500 mg calcium salts (lactate, gluconate, and carbonate) with atenolol (100 mg) reduced plasma levels of atenolol by 51%, and elimination half-life increased to a mean of 11.0 hours (vs. 6.2 hours with atenolol alone). The prolongation of elimination half-life induced by calcium coadministration led to atenolol cumulation during a subsequent 6-day course. Furthermore, exercise tachycardia was lower 12 hours after atenolol and calcium than with atenolol alone. Gugler and Allgayer[53] reported that later pharmacokinetic research involving calcium antacids did not confirm an interaction with atenolol.

Direct evidence is lacking demonstrating any interaction between calcium and other systemic beta blockers.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing atenolol or related beta blockers should advise patients to separate intake of the medication by at least 1 hour before or 2 hours after calcium supplements (or antacids). Prudence also suggests that physicians check the blood pressure of such patients before and after the initiation of calcium administration during beta-blocker therapy.

Well-designed clinical trials using specific forms of calcium are warranted to determine patterns of interaction, factors influencing clinical significance, and clinical responses to ensure efficacy of both beta blockers and calcium supplementation.

Bile Acid Sequestrants

See Cholestyramine, Colestipol, and Related Bile Acid Sequestrants.

Bisphosphonates

Evidence: Alendronate (Fosamax), etidronate (Didronel), risedronate (Actonel).

Extrapolated, based on similar properties: Clodronate (Bonefos, Ostac), ibandronate (Bondronat, Boniva), tiludronate (Skelid), zoledronic acid (Zometa).

Similar properties but evidence lacking for extrapolation: Pamidronate (Aredia).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:
2. Probable or
1. Certain

Evidence Base:
◉ **Emerging** or
● **Consensus**

Effect and Mechanism of Action

The ability of bisphosphonates to effectively inhibit osteoclastic activity and bone resorption, maintain healthy bone mineralization, and produce substantial gains in bone mass depends on the presence of adequate vitamin D and other nutrients (e.g., protein, calcium, phosphorus).[77,78] Calcium, the principal element in bone, can only be absorbed in the brush border of the intestinal mucosa when vitamin D is present. Notably, bisphosphonates have been used effectively to treat the more resistant cases of vitamin D–induced hypercalcemia.

Research

All currently approved bone-active pharmacological agents have been studied only in conjunction with supplemental calcium; newer anabolic agents increase mineral demand in skeletal tissue and will thus require even higher levels of calcium repletion.[79] The consensus underlying the fundamental importance of vitamin D and calcium nutriture is underscored by the observation that when Greenspan et al.[80] investigated the relative efficacy of hormone replacement therapy (HRT, conjugated estrogen with or without medroxyprogesterone) plus alendronate, HRT alone, alendronate alone, or placebo on spine and hip BMD in 373 osteopenic elderly women, all subjects received calcium and vitamin D supplements. After 3 years, dual-energy x-ray absorptiometry (DXA) scans showed that participants taking combination therapy had greater improvements in BMD at the hip and spine than did those participants taking HRT or alendronate alone, or placebo, all with calcium and vitamin D.

In an uncontrolled clinical trial involving osteoporosis patients with a poor response to bisphosphonate therapy, Heckman et al.[81] found that the addition of 25 μg (1000 IU) vitamin D daily to the bisphosphonate regimen resulted in significantly increased BMD of the lumbar spine after 1 year.[81] In a randomized, double-blind trial involving 48 osteopenic and osteoporotic women, Brazier et al.[82] compared one group who received alendronate, 10 mg once daily, along with 500 mg elemental calcium daily and 10 μg (400 IU) cholecalciferol (vitamin D_3) twice daily for 3 months, and a second group who received the same dosage of alendronate and calcium but placebo instead of the vitamin D. All subjects had low BMD, serum 25-hydroxyvitamin D_3 (25-OHD, calcifediol) less than 12 μg/L, and dietary calcium intake less than 1 g/day. Although markers of bone remodeling such as serum and urinary CTX and urinary NTX (C- and N-terminal telopeptides of type I collagen) were dramatically and significantly decreased after as soon as 15 days of treatment and remained decreased throughout treatment in both groups, the group also receiving the vitamin D demonstrated a more pronounced effect, particularly after 1 month, for the bone resorption markers serum CTX and urinary NTX. These researchers concluded that coadministration of calcium and vitamin D could be appropriate in elderly women with calcium and vitamin D insufficiencies being treated with alendronate, to achieve rapid reduction of bone loss.[82]

Paget's disease is characterized by abnormal osteoclastic bone resorption, and bisphosphonates are powerful and selective inhibitors of osteoclastic bone resorption. In a randomized, placebo-controlled, double-blind study involving 15 patients with Paget's disease, O'Doherty et al.[83] observed that daily 1-hour infusions of alendronate caused small decreases in serum calcium, serum phosphate, and urinary calcium excretion.

Reasner et al.[84] observed acute changes in calcium homeostasis as a result of 7 days' treatment with risedronate. A decrease in serum calcium was accompanied by evidence of inhibition of bone resorption in patients with mild primary hyperparathyroidism, a condition typically characterized by hypercalcemia. Oral calcium partially suppressed serum hyperparathyroid hormone in both controls and subjects receiving risedronate. Although patients treated with risedronate had normal fasting serum calcium levels, serum calcium values in these normocalcemic patients were labile after oral calcium. After administration of 2 g calcium daily, serum calcium levels in risedronate-treated patients were similar to those in untreated patients with primary hyperparathyroidism. The authors interpreted these findings to suggest that serum calcium levels are likely to fluctuate in risedronate-treated patients with normal fasting serum calcium during postprandial periods. Further long-term research is warranted to determine whether the lability in serum calcium observed in the short term has clinical significance, how risedronate would influence serum calcium levels and BMD with extended use, and what clinical implications would be for concomitant calcium.

Some patients with prostate carcinoma and a diffuse metastatic invasion of the skeleton exhibit indirect biochemical and histological indications of osteomalacia. Bisphosphonates are known to cause symptomatic hypocalcemia in prostate cancer patients with diffuse skeletal metastases. Bisphosphonate administration can aggravate osteomalacia and give the appearance of symptomatic hypocalcemia because of the transient,

striking prevalence of osteoblastic activity over bone resorption by osteoclasts, which are inhibited by bisphosphonate drugs. Calcium supplementation is often considered as contraindicated in individuals with prostate cancer. However, concomitant use with bisphosphonates has been proposed as a means of inhibiting osteoclastic activation that often precedes the abnormal osteoblastic bone formation within metastases. Thus, Adami[85] suggested that coadministration of high doses of calcium with alendronate therapy in prostate cancer patients with bone metastases (with evidence of osteomalacia) might contribute to improved clinical outcomes.

In regard to men with nonmetastatic prostate cancer, findings from a small, randomized, double-blind controlled trial conducted by Nelson et al.[86] showed that treatment with 70 mg alendronate weekly, plus daily calcium and vitamin D, reversed bone loss in men receiving antiandrogen therapy. In contrast, the 56 subjects taking placebo, calcium, and vitamin D lost BMD during the same period. Notably, among these 112 men, average age 71, only 9% had normal bone mass, whereas 52% had low bone mass and 39% developed osteoporosis after an average 2 years of androgen-deprivation therapy (ADT).[86]

In a nonblinded, randomized prospective trial examining BMD in 211 long-term adult renal transplant recipients, Jeffery et al.[87] compared calcitriol and alendronate and found that osteopenia or osteoporosis, which are experienced by the majority of such patients, can be effectively treated with calcium plus calcitriol or alendronate.

In a randomized trial involving 154 patients with Crohn's disease, Siffledeen et al.[88] investigated the efficacy of etidronate plus calcium and vitamin D for treatment of low BMD. The subjects, most of whom had T scores in the osteopenic range (−1.5 to −2.5), were administered etidronate (400 mg orally) or placebo for 14 days, and then both groups were given daily calcium (500 mg) and vitamin D (400 IU) for 76 days in a treatment cycle repeated every 3 months for 2 years. After 24 months, BMD at the lumbar spine, ultradistal radius, and trochanter sites, but not the total hip, increased steadily, significantly, and similarly in both treatment arms. The findings from this trial demonstrate that, in patients with low BMD on absorptiometry, treatment with calcium and vitamin D alone will increase bone density by about 4% per year and that adding etidronate to the treatment program does not appear to enhance the effects of calcium and vitamin D.[88] In an accompanying editorial on the preeminence of calcium and vitamin D in limiting fracture risk in Crohn's (inflammatory bowel) disease (IBD), Bernstein[89] commented that this study provides reassurance that bisphosphonates are "rarely needed in IBD patients most of whom have T scores greater than −2.5, and many of whom are using corticosteroids to some extent."

The National Osteoporosis Risk Assessment (NORA) Study, a longitudinal, observational study of osteoporosis among postmenopausal women in primary care practices across the U.S., reported in 2005 that 58% of women who might benefit from the osteoporosis treatment do not receive any of the standard medications, and when HRT is included, the number falls to 38%.[90]

Reports

In a review of 63 cases, Ruggiero et al.[91] described a pattern of osteonecrosis of the jaw (ONJ), an otherwise rare condition, in patients undergoing prolonged treatment with bisphosphonates. Fifty-six patients had received intravenous bisphosphonates for at least 1 year, and seven patients were receiving chronic oral bisphosphonate therapy. Fifty-five of these patients were being treated for various forms of cancer, one for osteoporosis. ONJ has occurred spontaneously in a significant number of patients. However, most cases have been associated with infections after dental surgeries, in patients on bisphosphonate therapy. The authors recommend that all patients on long-term bisphosphonate therapy have two or three preventive dental visits per year, and that physicians be watchful for any early signs of ONJ, such as tooth pain, swelling, numbness of the lip and chin, or pain in the jaw.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Calcium and vitamin D are essential for maintaining bone mass and density and imperative to the success of drug therapies for inducing bone augmentation.[78] Deficiencies of both nutrients are common in the patient populations at highest risk for bone loss. The importance of exercise and sound nutrition (including adequate protein, calcium, and phosphorus intake) as foundational cannot be overemphasized and is supported by growing evidence. Calcium has a clearly demonstrated effect of enhancing estrogen's effects on bone metabolism. Further, most research indicates that consistent exposure to sunlight (excluding winter in northern latitudes) provides a safe and effective, as well as otherwise beneficial, method of elevating vitamin D levels. Daily doses of 1500 mg calcium and 800 IU vitamin D provide prudent nutritional support for osteoporosis prevention and treatment, or more exactly, 30 to 40 mmol calcium with sufficient intake vitamin D daily, to maintain serum 25(OH)D levels above 80 nmol/L (~30 μg/L).[79]

Thus, a synergistic combination of oral calcium and vitamin D, within the context of an active lifestyle and nutrient-rich diet, constitutes the core proactive intervention within integrative therapeutics for all individuals at high risk for osteoporosis, or a foundational treatment for diagnosed bone loss. Notably, low serum vitamin D levels have been associated with the incidence of falls in older women,[92] and vitamin D has been found to be helpful in reducing the incidence of falls, a major factor in fracture risk, by improving muscle strength, walking distance, and functional ability.[93] Also, hormone supplementation or replacement regimens (conventional HRT, bio-identical estrogens/progesterone, herbal hormone precursors/modulators) should be considered if indicated in women. In addition to these primary and secondary therapies, the use of a bisphosphonate can provide a potent intervention in reversing bone loss and supporting healthy bone mass.

Coadministration of bisphosphonates and calcium in patients with Paget's disease or prostate carcinoma requires close supervision and regular monitoring within the context of an integrative team of health care professionals trained and experienced in multidisciplinary therapeutics, including conventional pharmacology and nutritional therapeutics.

Oral calcium preparations need to be taken at least 2 hours before or after the bisphosphonate to avoid pharmacokinetic interference. However, the timing of oral vitamin D intake need not be managed because no evidence has indicated potential pharmacological interference with bisphosphonates or other components of the treatment. It is generally recommended to take alendronate or etidronate with a full glass (6-8 ounces) of plain water on an empty stomach and to avoid the recumbent position for at least 30 minutes to prevent potential severe esophageal irritation associated with incomplete transfer of the tablet to the stomach.

Calcitonin

Calcitonin (Calcimar, Miacalcin Nasal).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
2. Probable

Evidence Base:
◉ **Emerging** or
● **Consensus**

Effect and Mechanism of Action

Calcitonin is a polypeptide hormone made by the thyroid gland that decreases bone resorption and reduces bone loss. Adequate calcium intake appears to enhance the bone-sparing benefit of calcitonin, particularly on the spine.

Research

Nieves et al.[94] reviewed six published clinical trials evaluating the effects of 200 IU intranasal salmon calcitonin in combination with calcium administration (total 1466 mg/day) as well as one using calcitonin alone. They observed that bone mass of the lumbar spine increased 2.1% with calcitonin and calcium, compared with −0.2% per year in those receiving calcitonin alone. These researchers concluded that the available data suggest that a high calcium intake potentiates the positive effect of calcitonin on bone mass of the spine. They also noted that these findings suggest that the dosage of nasal calcitonin used (200 IU) may be suboptimal.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing intranasal calcitonin for prevention or treatment of osteoporosis are advised to coadminister calcium (400–500 mg three times daily).

Calcium Acetate

Calcium acetate (Phoslo).

Interaction Type and Significance

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

Probability:
2. Probable

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Concomitant use of calcium supplements during calcium acetate administration can produce an additive effect that may be harmful in some individuals, especially in the context of renal failure.

Calcium acetate supplies an extremely bioavailable source of calcium because it ionizes readily and the acetate is quickly burned in the Krebs cycle, thereby providing a ready supply of calcium ions to complex with free phosphorus in renal patients with hyperphosphatemia. Care must be taken not to administer calcium if the serum calcium times phosphorus ($Ca \times PO_4$) product is greater than 70; calcium phosphate deposition in soft tissues is likely at this level. Aluminum salts were previously used for this purpose but were largely replaced by calcium acetate as the toxicity of aluminum became recognized.

Research

Although the additive interaction between these agents is considered formulaic and highly probable to result in clinically significant adverse effects, evidence from clinical trials focused directly on this interaction is lacking.

Clinical Implications and Adaptations

Physicians prescribing calcium acetate are advised to be watchful for indications of hypercalcemia (e.g., anorexia, depression, poor memory, muscle weakness), monitor serum calcium and phosphorus levels, and warn patients to avoid calcium supplementation. This interaction may be relevant only to the population with chronic renal insufficiency. It is not known whether it applies to those with normal renal function because clinical trials addressing this question are lacking. The probability of a clinically significant interaction involving hypercalcemia after concomitant intake of calcium acetate and other calcium supplements in normal individuals is low.

Cholestyramine, Colestipol, and Related Bile Acid Sequestrants

Evidence: Cholestyramine (Locholest, Prevalite, Questran), colestipol (Colestid).
Extrapolated, based on similar properties: Colesevelam (WelChol).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:
3. Possible

Evidence Base:
○ **Preliminary** or
◉ **Emerging**

Effect and Mechanism of Action

The primary effect on calcium levels may be caused by lowered absorption of vitamin D under the influence of bile acid sequestrants. Medications in this class can bind calcium and thereby impair its absorption; they may also increase the loss of calcium in the urine.

Research

Diminished intestinal absorption of vitamin D, osteomalacia, and other metabolic alterations have been reported with long-term use of bile acid sequestrants. Colestipol lowers vitamin D absorption and thus adversely affects calcium metabolism. In vitro research indicates that cholestyramine causes appreciable binding of calcium (from calcium chloride) and thereby decreases absorption.[95] Animal studies suggest that cholestyramine may deplete calcium (and zinc). Watkins et al.[96] observed that rats fed cholestyramine for 1 month had a net negative balance for calcium, increased urinary excretion of calcium and magnesium, and a lower net positive balance for magnesium, iron, and zinc than the controls. They attributed these alterations in calcium, magnesium, and zinc metabolism to impaired vitamin D absorption from the intestine, followed by increased PTH secretion.

One study investigating possible malabsorption of minerals and vitamins in young patients with familial hypercholesterolemia after 5 years of colestipol therapy found no significant changes in plasma levels of calcium, PTH, and vitamin D, as well as other nutrients. However, changes in most of these parameters would not be predicted, and potential effects on bone mass were not assessed.[97] However, Tonstad et al.[98] conducted a study of 37 boys and 29 girls age 10 to 16 years with familial hypercholesterolemia, first in an 8-week, double-blind,

placebo-controlled protocol, then in open treatment for 44 to 52 weeks. After 1 year of colestipol, those who took 80% or more of the prescribed dose had a greater decrease in serum 25-OHD levels than those who took less than 80%. Secondary effects on calcium metabolism and bone health were not investigated directly, but the observed adverse effect on vitamin D would be predicted to impair calcium absorption. Also, levels of serum folate, vitamin E, and carotenoids were reduced in the colestipol group.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing bile acid sequestrants are advised to recommend supplementation with calcium (500 mg twice daily) along with vitamin D and other fat-soluble nutrients. Although modest supplementation with vitamin D (10-20 μg or 400-800 IU daily) may be advisable for many individuals, particularly those at high risk for deficiency sequelae, consistent exposure to sunlight (without sunscreen) may be sufficient to maintain healthy vitamin D levels and can be combined with the exercise usually critical to those being prescribed bile acid sequestrants. Exposure to sunlight in the winter months of northern latitudes, however, is likely to be insufficient to maintain adequate vitamin D levels, making it necessary to use dietary supplements or a rich natural source of vitamin D, such as cod liver oil, at least 2 hours before or after the bile sequestrant agents.

Corticosteroids, Oral, Including Prednisone

Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), hydrocortisone (Cortef), methylprednisolone (Medrol) prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).

Similar properties but evidence indicating no or reduced interaction effects: Inhaled or topical corticosteroids.

Effect and Mechanism of Action

Corticosteroids can impair calcium absorption and interfere with both calcium and vitamin D metabolism, thereby adversely affecting bone density and potentially other calcium-related functions. Several mechanisms have been implicated in these adverse effects. Corticosteroids interfere with the activation of vitamin D and thereby impair calcium absorption and contribute to secondary hyperparathyroidism. Decreases in tubular calcium reabsorption with increases in urinary excretion of calcium have also been demonstrated. Thus, increased bone resorption is caused by decreased calcium absorption and increased urinary calcium excretion, leading to secondary hyperparathyroidism. Furthermore, corticosteroids increase the risk for developing osteoporosis not only by altering normal calcium metabolism, but also by reducing osteoblast activity. Also, steroids, even in low dose, can decrease osteocalcin, P1CP, and ALP.[99-112]

Research

Oral corticosteroids can adversely affect BMD and increase the risk of osteoporosis through their impact on both calcium and vitamin D. Numerous studies have demonstrated adverse effects on vitamin D and its functions due to steroid therapy; these are reviewed in the vitamin D monograph. Under active transport conditions, administration of corticosteroids produces a decrease of net calcium absorption by depressing vitamin D–dependent intestinal calcium absorption and increasing vitamin D–independent calcium backflux.[101,102,109,113]

Corticosteroids can adversely affect both bone formation and resorption. Serum osteocalcin, a sensitive marker of bone formation (and a vitamin K–dependent protein), is reduced with both short-term and chronic glucocorticoid treatment, corresponding to observed effects of reduced bone formation. In a double-blind placebo-controlled study involving 15 normal subjects, Nielsen et al.[106] found that oral prednisone at two dosage levels, 2.5 mg and 10 mg, proportionately inhibited serum osteocalcin levels within 3 to 4 hours and even reversed the normal nocturnal rise within the circadian rhythm of serum osteocalcin levels. In a 1998 study, Lems et al.[112] reported that low-dose (10 mg/day) prednisone (LDP) treatment led to a decrease in osteocalcin, P1CP, and ALP and an increase in urinary excretion of calcium. They concluded that LDP has a negative effect on bone metabolism because bone formation decreased and bone resorption remained unchanged or decreased slightly.

A strong trend in the cumulative research findings demonstrates that corticosteroids, especially long-term therapy or repeated use, can reduce bone density, cause development of corticosteroid-induced osteoporosis, and increase the risk of sustaining osteoporotic fractures.[110,114-118] By comparing asthmatic patients receiving long-term glucocorticoid therapy with a second group of age-matched and gender-matched asthmatic individuals not receiving these drugs, Reid et al.[115] measured a significant reduction in renal tubular calcium reabsorption in the glucocorticoid-treated patients. Tsugeno et al. [117] measured relative cortical volume (RCV) and other parameters in 86 postmenopausal asthmatic women taking high-dose oral steroid (> 10 g cumulative oral prednisolone) and 194 age-matched controls. Individuals treated with high doses of oral steroid demonstrated a significantly increased risk of fracture compared with control women after adjustment was made for years since menopause, body mass index, and RCV. In a study involving 117 patients taking oral corticosteroids for chronic lung disease, Walsh et al.[119] found that 58% had osteoporosis (a T score of less than −2.5) and 61% had a vertebral fracture, and that cumulative prednisolone dose was strongly associated with vertebral fracture. After analyzing the composite data, they concluded that "cumulative prednisolone dose is strongly related to fracture risk, and this effect is independent of its more modest impact on BMD." In a retrospective, cohort study, Steinbuch et al.[120] observed that oral glucocorticoid use is associated with an increased risk of fracture. Specifically, they found that dose dependence of fracture risk was observed for hip, vertebral, nonvertebral, and any fractures. Extended duration and continuous pattern of steroid use demonstrated a fivefold increase in risk of hip fracture and 5.9-fold increase in risk of vertebral fracture. Together, the combined effect of higher dose, longer duration, and continuous pattern further increased relative risk estimates to

sevenfold for hip fractures and seventeenfold for vertebral fractures. Thus, a consensus has emerged confirming a strong association between oral corticosteroid therapy, especially chronic or repeated use, and adverse effects on calcium balance, BMD, and fracture susceptibility. Vitamin D deficiency is also associated with increased fracture risk as well as risk of falls. Overall, the degree of bone loss usually parallels the cumulative corticosteroid dose, and the highest rate of bone loss is observed in the first 3 to 6 months of therapy.

The adverse effects associated with inhaled corticosteroids (ICs) are generally considered as less common, less severe, and significantly less likely risk to contribute to fractures. For example, in a group of postmenopausal women, Elmstahl et al.[122] found no difference in BMD between the subset using ICs and unexposed control subjects, and no dose-response relationship between IC therapy and BMD.

The predominant weight of evidence suggests that coadministration of calcium and vitamin D can mitigate and possibly reverse loss of bone density and risk of osteoporosis associated with long-term oral corticosteroid therapy. In particular, the adverse effects of glucoactive corticosteroids on intestinal calcium transport and bone turnover can usually be counteracted by the combined administration of supplemental doses of calcium and physiologic doses of $25(OH)D_3$.[102,123,124] Reid and Ibbertson[125] studied the metabolic effects of administering 1 g of elemental calcium daily in 13 steroid-treated patients. After 2 months, they concluded that "calcium supplementation suppresses bone resorption without detectable suppression of indices of bone formation" and was therefore likely to result in increased bone mass. In a 2-year, randomized, double-blind, placebo-controlled trial involving 96 patients administered low-dose prednisone (mean dosage, 5.6 mg/day) for rheumatoid arthritis, Buckley et al.[113] found that subjects who received concomitant calcium carbonate (1000 mg) and vitamin D_3 (500 IU) daily maintained their bone density and gained BMD in the lumbar spine and trochanter. Subsequently, in a multiphase observational trial involving eight healthy, young male volunteers administered low-dose prednisone (10 mg/day), Lems et al.[126] found PTH (insignificantly) increased during prednisone (+19%) and prednisone plus 500 mg/day calcium (+14%), but decreased during supplementation with calcitriol (−16%) and calcium/calcitriol (−44%). The increase in PTH during prednisone could be prevented by coadministration of calcitriol and calcium.

Several recent reviews have come to somewhat divergent conclusions. Amin et al.[127] conducted a meta-analysis of all randomized controlled trials lasting at least 6 months (and reporting extractable results). They applied change in lumbar BMD as the primary outcome measure and observed that coadministration with the combination of calcium and vitamin D provided a "moderate beneficial effect," compared with placebo or calcium alone, in protecting against corticosteroid-induced osteoporosis. They concluded that "treatment with vitamin D plus calcium, as a minimum, should be recommended to patients receiving long-term corticosteroids." In contrast, in a review of the evidence on calcium supplementation for corticosteroid-induced bone loss during steroid therapy, also published in 1999, Adachi and Ioannidis[90] declared, "Calcium prophylaxis alone, when patients start corticosteroids, is associated with rapid rates of spinal bone loss and offers only partial protection from corticosteroid-induced spinal bone loss. Though calcium supplementation may have some benefit, it clearly cannot completely prevent corticosteroid-induced bone loss." Commenting on studies showing benefit from calcium supplementation, they also observed that "caution should be taken when interpreting these results, since bone loss generally tapers or plateaus after the first 12 months of corticosteroid treatment; as such, any therapy might show benefit." They also questioned the methodology used in assessing bone density, particularly measurements at the radius rather than the spine. They also questioned the adequacy of calcium and vitamin D in counteracting the bone loss caused by corticosteroids and suggested the need for further support, including activated vitamin D.[90] In a 2000 Cochrane review, Homik et al.[128] evaluated five trials (totaling 247 patients) for lumbar and radial bone BMD after a minimum of 2 years supportive treatment. Their meta-analysis demonstrated "a clinically and statistically significant prevention of bone loss at the lumbar spine and forearm with vitamin D and calcium in corticosteroid treated patients." Noting the low cost and limited toxicity, they recommended that "all patients being started on corticosteroids should receive prophylactic therapy with calcium and vitamin D."

The issue of which forms of calcium and vitamin D provide the most effective protection with the least risk of adverse effects remains unresolved. Evidence is lacking from well-designed trials focusing on which of the of various forms of calcium, or combinations thereof, is most efficacious against steroid-induced bone loss, establishing appropriate dosage level, and determining possible variables in patient characteristics influencing efficacy. The question of safety and efficacy in selecting an appropriate form of vitamin D is similarly unresolved and remains contentious within conventional medicine. Numerous researchers and commentators have voiced concern over the risk of hypercalciuria and hypercalcemia when coadministering both calcium and vitamin D and noted experiences or cited reports of such.[111] Although the weight of evidence indicates that calcitriol ($1,25\text{-}OH_2D_3$), the most active form of vitamin D, may be the most effective, it also carries greater risk than calcifediol (25-OHD) or other forms of vitamin D.[129]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The primary concern regarding calcium in the context of corticosteroid therapy is bone loss through decreased absorption and increased urinary excretion. Corticosteroid-induced osteoporosis is a serious disorder that results in significant long-term morbidity. Optimal management strategies to prevent bone loss should include the use of the lowest efficacious dose of steroid medications and shortest duration of administration.

Prevention of adverse effects should include adequate calcium intakes from dietary and supplemental sources totaling 1000 to 1500 mg of calcium daily in conjunction with at least 500 IU of vitamin D daily, although much higher doses may be necessary in the context of a preexisting 25-OHD deficiency.[41] Monitoring serum levels of both 25-OHD and $1,25\text{-}OH_2D$ (activated form of vitamin D) is appropriate, and prescription of calcitriol may be necessary if a deficiency is indicated. If 25-OHD levels are low (< 50 nmol/L), correction with up to 7000 IU vitamin D_3 daily, or 50,000 IU vitamin D_2 weekly, for 1 to 2 months will correct the 1,25-dihydroxycholecalciferol level in patients with normal renal function. Often the $1,25\text{-}OH_2D$ level is maintained, even in the face of a 25-OHD deficiency, due to increased secretion of PTH, which speeds up renal conversion of 25-OHD to the active form. Thus, measuring intact PTH as well as both forms of vitamin D provides the most complete picture of vitamin D status.[41] It is also prudent to monitor for hypercalciuria and hypercalcemia when supplementing with both calcium and vitamin D. Physicians prescribing steroids for longer than 2 weeks should encourage all patients to modify their lifestyles, including smoking cessation and limitation of alcohol

consumption. The importance of mild to moderate weight-bearing exercise cannot be overemphasized; 30 minutes to 1 hour every day, particularly with sunlight exposure, should be strongly encouraged, if feasible. However, individuals with known or potential bone loss should be advised to develop an exercise program under the supervision of a physician or other health care professional familiar with the increased risks of fracture associated with long-term use of steroids.

EDTA

EDTA (Ethylenediaminetetraacetic Acid)

Probability: **1. Certain**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

EDTA binds to calcium and thereby increases calcium excretion.

Research

The chelation function of EDTA is central to its primary pharmacological action in therapeutic application.[130] As such, chelation with EDTA is considered among standard causes of hypocalcemia from increased loss of calcium, and EDTA is used experimentally to induce hypocalcemia.[131] However, in the presence of heavy metals, which bind more tightly to EDTA than calcium, the heavy metals will preferentially bind.

Experiments by Foreman and Trujillo[132] (1954) found that EDTA demonstrated 45% to 72% efficiency chelating Ca^{++} and that up to 3.2 mg/dL Ca^{++} is bound during infusion. Calcium excretion changed over time after chelation, with 28% excess Ca^{++} excreted during infusion, 60% excess Ca^{++} excreted 6 hours after infusion, and 12% excess Ca^{++} excreted 6 to 12 hours after infusion. Overall, serum ionized Ca^{++} was significantly reduced. Numerous responses to EDTA-induced hypocalcemia have been documented, including ionization of protein-bound and soft tissue Ca^{++}, induction of PTH secretion and vitamin D_3 synthesis, stimulation of bone resorption and osteoclast differentiation, and suppression of osteoblast differentiation.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Chelation with EDTA or other agents requires appropriate training and proper monitoring. Assessment of calcium levels is appropriate, and clinical responses will vary accordingly. When properly administered, EDTA chelation is considered unlikely to result in adverse reactions from hypocalcemia. Physicians who administer EDTA for chelation of heavy metals or other clinical applications routinely supplement their patients with minerals of nutritional importance.

ESTROGENS, PROGESTINS, AND ESTROGEN-PROGESTIN COMBINATIONS

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCept 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).

Hormone Replacement Therapy (HRT): Estrogen-Containing and Synthetic Estrogen and Progesterone Analog Medications

HRT, estrogens: Chlorotrianisene (Tace); conjugated equine estrogens (Premarin); conjugated synthetic estrogens (Cenestin); dienestrol (Ortho Dienestrol); esterified estrogens (Estratab, Menest, Neo-Estrone); estradiol, topical/transdermal/ring (Alora Transdermal, Climara Transdermal, Estrace, Estradot, Estring FemPatch, Vivelle-Dot, Vivelle Transdermal); estradiol cypionate (Dep-Gynogen, Depo-Estradiol, Depogen, Dura-Estrin, Estra-D, Estro-Cyp, Estroject-LA, Estronol-LA); estradiol hemihydrate (Estreva, Vagifem); estradiol valerate (Delestrogen, Estra-L 40, Gynogen L.A. 20, Progynova, Valergen 20); estrone (Aquest, Estragyn 5, Estro-A, Estrone '5', Kestrone-5); estropipate (Ogen, Ortho-Est); ethinyl estradiol (Estinyl, Gynodiol, Lynoral).

HRT, estrogen/progestin combinations: Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); conjugated equine estrogens and norgestrel (Prempak-C); estradiol and dydrogesterone (Femoston); estradiol and norethindrone, patch (CombiPatch); estradiol and norethindrone/norethisterone, oral (Activella, Climagest, Climesse, FemHRT, Trisequens); estradiol valerate and cyproterone acetate (Climens); estradiol valerate and norgestrel (Progyluton); estradiol and norgestimate (Ortho-Prefest).

HRT, estrogen/testosterone combinations: Esterified estrogens and methyltestosterone (Estratest, Estratest HS).

See also Medroxyprogesterone.

Effect and Mechanism of Action

Estrogen-containing medications can contribute to decreased BMD and increase the long-term risk of osteoporosis. Concomitant use of calcium (and vitamin D) supplements and exogenous estrogen may act synergistically to improve bone density and support the prevention and treatment of osteoporosis. Calcium, the principal element in bone, can only be absorbed in the brush border of the intestinal mucosa when vitamin D is present. Estrogen appears to enhance calcium absorption by increasing serum 1,25-dihydroxycholecalciferol [$1,25(OH)_2D$]. In contrast to the

beneficial effect on vitamin D (and calcium) metabolism exerted by estrogens, progestins may diminish that benefit. Estrogens may also contribute to an overall increase in calcium blood levels by decreasing urinary calcium loss. Overall, the ability of exogenous female hormones, particularly forms of estrogen, to effectively inhibit osteoclastic activity and bone resorption, maintain healthy bone mineralization, and support bone mass is inherently dependent on the presence of vitamin D, calcium, and other nutrients (e.g., protein, phosphorus).[77,78]

Research

In a randomized clinical trial, Teegarden et al.[132] studied the relationship between dietary calcium intake and BMD in 133 young women (18-30 years old) using oral contraceptives (OCs) who all were initially characterized by dietary calcium intake of less than 800 mg/day. The subjects were assigned to groups stratified by dietary intake: high calcium intake (1200-1300 mg/day), medium calcium intake (1000-1100 mg/day), and control (<800 mg/day). They found that higher levels of calcium intake, in the form of dairy products, positively impacted percent change of total-hip and total-body bone mineral density (BMD) and bone mineral content (BMC) and that such intake patterns "prevented a negative percent change in total hip and spine BMD" in women using OCs. They concluded: "Dairy product intake, at levels to achieve the recommended intakes of calcium, protected the total hip BMD and spine BMD from loss observed in young healthy women with low calcium intakes who were using [OCs]."[132]

The negative calcium balance usually associated with aging is accentuated in osteoporotic women who have decreased calcium absorption and decreased serum levels of $1,25(OH)_2D$. In a controlled trial involving 17 women with surgically induced menopause, Lobo et al.[134] (1985) observed that serum levels of $1,25(OH)_2D$ increased and urinary calcium loss decreased after 2 months of conjugated estrogens (0.625 mg daily).[134] Subsequently, several studies have investigated whether such elevated vitamin D levels might correspond with increased bone strength and reduced risk of fractures, and how such effect might vary given initial BMD status, for different individuals, under different HRT regimens, or with different forms of calcium.

Several studies have examined the role of estrogen in improving calcium balance in women with postmenopausal osteoporosis. In a randomized, double-blind, placebo-controlled trial involving 128 healthy Caucasian women over age 65 with low spinal BMD, Recker et al.[135] compared parameters of BMD and bone loss under continuous low-dose HRT (conjugated equine estrogen, 0.3 mg/day, and medroxyprogesterone, 2.5 mg/day) in conjunction with calcium and vitamin D versus placebo. Subjects in both groups were administered sufficient calcium to bring all calcium intakes above 1000 mg/day and oral 25-hydroxyvitamin D sufficient to maintain serum 25-OHD levels of at least 75 nmol/L. Through the course of 3.5 years of observation, significant increases were seen in spinal BMD as well as in total-body and forearm bone density, particularly among patients with greater than 90% adherence to therapy. Meanwhile, breast tenderness, spotting, pelvic discomfort, mood changes, and other symptoms typically associated with HRT were mild and short-lived under this relatively low-dose regimen. These authors concluded that "continuous low-dose HRT with conjugated equine estrogen and oral medroxyprogesterone combined with adequate calcium and vitamin D provides a bone-sparing effect that is similar or superior to that provided by other, higher-dose HRT regimens in elderly women" and is well tolerated by most patients.[135]

In a 6-month placebo-controlled clinical trial involving 21 postmenopausal women with osteoporosis, Gallagher et al.[136] observed that conjugated equine estrogen increased both calcium absorption and serum vitamin D levels [1,25-$(OH)_2D$]. Subsequently, these researchers investigated the roles of estrogen deficiency and declining calcium absorption caused by reduced activated vitamin D (calcitriol) levels or intestinal resistance to calcitriol as central factors in age-related bone loss. In a randomized, double-blind, placebo-controlled trial involving 485 elderly women (age 66-77) with normal bone density for their age, they compared the effects of estrogen replacement therapy (ERT, 0.625 mg conjugated estrogens daily for women without a uterus) and HRT (ERT plus 2.5 mg medroxyprogesterone acetate daily for women with a uterus) with or without calcitriol (1,25-OHD) versus placebo. HRT alone and in combination with calcitriol were both highly effective in reducing bone resorption and increasing BMD at the hip and other key sites. In particular, calcitriol was effective in increasing BMD in the femoral neck and spine. In the adherent women, the combination of ERT/HRT and calcitriol increased BMD in the total hip and trochanter significantly more than did ERT or HRT alone, particularly in women who were adherent to treatment.[137]

Among several benefits observed in perimenopausal and postmenopausal women, calcium coadministration enhances the beneficial effect of exogenous estrogen on bone mass.[138,139] Nieves et al.[94] reviewed and analyzed 31 published clinical trials that measured bone mass of postmenopausal women from at least one skeletal site and determined that high calcium intake from diet or supplements potentiates the positive effect of estrogen on bone mass at all skeletal sites. In a retrospective study involving 315 women, Pines et al.[140] observed that early postmenopausal women taking calcium supplements with estradiol (or conjugated estrogens) demonstrate significantly greater gains in BMD than women taking HRT alone and concluded that calcium supplementation should be recommended in all postmenopausal women. In a placebo-controlled randomized trial involving 63 postmenopausal women, Ruml et al.[141] found that calcium citrate (400 mg twice daily) averted bone loss and stabilized BMD in the spine, femoral neck, and radial shaft in women relatively soon after menopause. They attributed this bone-sparing action to the inhibition of bone resorption from PTH suppression.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Calcium intake, along with vitamin D, remains the fundamental component supporting bone health at all ages and for both genders and is of particular importance in preventing bone loss in postmenopausal women. Requirements for healthy calcium intake begin at an early age because OC use may prevent attainment of maximal peak bone mass in young women. For women in postmenopausal years, HRT has been the mainstay of osteoporosis prevention but is limited because of dose-related risks, adverse effects, and patient acceptance. Estrogen may improve calcium absorption, vitamin D activity, and bone metabolism, but it remains important for women taking estrogen to maintain adequate calcium intake through diet and supplementation. Deficiencies of both nutrients are common in the patient populations at highest risk for osteoporosis. Calcium and estrogen have a clearly demonstrated synergistic effect of enhancing each other's effects on bone metabolism. Nevertheless, prudent nutritional support for osteoporosis

prevention and treatment can be provided through diet or supplementation including 1500 mg/day of calcium and 800 IU (20 µg) vitamin D, or more exactly, sufficient intake vitamin D per day to maintain serum 25(OH)D levels above 80 nmol/L (30 ng/ml or µg/L).[79]

Thus, a synergistic combination of oral calcium and vitamin D, within the context of a calcium-rich diet and an active lifestyle, constitutes the core proactive intervention within integrative therapeutics for all women using exogenous estrogens, particularly individuals at high risk for osteoporosis, or a foundational treatment for diagnosed bone loss. Additionally, in the treatment of menopausal women, hormone supplementation or replacement regimens (conventional HRT, bio-identical estrogens/progesterone, isoflavones, herbal hormone precursors/modulators) may achieve similar effects, but conclusive evidence is lacking; further research through well-designed clinical trials is warranted. Bisphosphonates and calcitonin, as well as magnesium, boron, and other nutrients, may also play a role as options within a comprehensive approach to bone health through the later phases of the life cycle in both women and men.

The importance of exercise and sound nutrition as foundational cannot be overemphasized and is supported by growing evidence. Weight-bearing exercise is fundamental to maintaining BMD and reducing bone loss.[142-144] Vitamin D nutriture and adequate protein and phosphorus intake are also essential. Further, most research indicates that consistent, moderate exposure to sunlight provides a safe and effective, as well as otherwise beneficial, method of elevating vitamin D levels. Ultimately, prevention through exercise and calcium intake during the life stage of skeletal development is most important for establishing peak bone density. Patients should be educated and encouraged to make these lifelong habits.

Fluoroquinolone (4-Quinolone) Antibiotics

Cinoxacin (Cinobac, Pulvules), ciprofloxacin (Ciloxan, Cipro), enoxacin (Penetrex), gatifloxacin (Tequin), levofloxacin (Levaquin), lomefloxacin (Maxaquin), moxifloxacin (Avelox), nalidixic acid (Neggram), norfloxacin (Noroxin), ofloxacin (Floxin, Ocuflox), sparfloxacin (Zagam), trovafloxacin (Trovan).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **1. Certain**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

The 3-carbonyl and 4-oxo functional groups on quinolone antibiotics form a chelate with calcium and other divalent metal cations, such as aluminum, copper, iron, magnesium, manganese, and zinc. This binding process can substantially interfere with the absorption, bioavailability, and activity of both the antimicrobials in this class and the supplemental calcium.

Research

The ability of multivalent cations to reduce the absorption and serum levels of oral quinolone antibiotics is well established.[145-156] However, much research has involved mineral-based antacids rather than nutritional supplements; the limitations of extrapolating these data have not been analyzed. This interaction appears to have the greatest clinical significance with aluminum and magnesium ions, occurs to a lesser extent with bismuth and calcium ions, and is probably nonexistent with sodium ions. The observed reduction in quinolone absorption can significantly affect peak concentration (C_{max}) and percent bioavailability and in some circumstances will inhibit the therapeutic effectiveness of the antibiotic. Calcium intake appears to affect the rate, but not the extent, of moxifloxacin absorption.[157] Experimental data indicate that the degree of this interference is variable for different medications, with calcium-containing antacids reducing quinolone bioavailability to the following percentages: lomefloxacin (98%), levofloxacin (97%), ciprofloxacin (59%), and norfloxacin (37%).[150,152,154,158-162]

In studies with rats and human volunteers, Sanchez Navarro et al.[163] found that coadministration of 500 mg/L calcium carbonate ($CaCO_3$) to healthy volunteers significantly reduced the urinary excretion of 250 mg/L ciprofloxacin, although neither the fraction of absorbed dose nor the half-life was greatly affected. They concluded that calcium therefore shares the same propensity as other cations in impairing the absorption of ciprofloxacin. However, Lomaestro and Bailie[164] found that repeated doses of calcium carbonate, administered 2 hours before ciprofloxacin, did not significantly alter the relative bioavailability of ciprofloxacin. Pletz et al.[165] compared the effect different timing of calcium carbonate intake on the oral bioavailability of gemifloxacin. In an experiment involving 16 volunteers, gemifloxacin was administered alone, 2 hours before, simultaneously, or 2 hours after calcium carbonate. Only simultaneous coadministration of calcium carbonate reduced C_{max} (−17%) and AUC (−21%) significantly.

Calcium depletion resulting from chelation by this class of medications has not been studied per se. Although plausible, such an adverse effect on calcium balance is highly improbable given the normal physiological controls on blood calcium levels and the limited duration of standard drug use. Long-term quinolone therapy and simultaneous oral intake could theoretically contribute to bone loss.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians treating patients for serious infections with quinolone antibiotics should advise them to refrain from ingesting calcium (and all other divalent mineral cation) supplements during therapy to avoid interfering with the absorption and thus the antimicrobial action of the medication. If this is not possible, administration of the medication 2 hours before or 6 hours after ingestion of an oral calcium supplement is suggested and can effectively minimize risk of an adverse interaction. This recommendation also applies to intake of calcium-containing antacids and calcium-rich or calcium-fortified foods. Monitor for decreased therapeutic effects of oral quinolones if inadvertently administered simultaneously with oral calcium supplements or calcium antacids.

GASTRIC ACID–SUPPRESSIVE MEDICATIONS

Cimetidine and Related Histamine (H_2) Receptor Antagonists

Evidence: Cimetidine (Tagamet; Tagamet HB).

Extrapolated, based on similar properties: Famotidine (Pepcid RPD, Pepcid, Pepcid AC), nizatidine (Axid, Axid AR), ranitidine bismuth citrate (Tritec), ranitidine (Zantac).

Omeprazole and Related Proton Pump Inhibitors

Evidence: Omeprazole (Losec, Prilosec).
Similar properties but evidence lacking for extrapolation: Esomeprazole (Nexium), lansoprazole (Prevacid, Zoton), pantoprazole (Protium, Protonix, Somac), rabeprazole (AcipHex, Pariet).

Probability:
2. Probable or
3. Possible

Evidence Base:
◉ **Emerging** and
▽ **Mixed**

Effect and Mechanism of Action

Cimetidine may significantly decrease net calcium absorption and transport across the intestinal lumen to the mucosa, an action that may be secondary to its effect on the release of parathyroid hormone (PTH) or an effect on vitamin D metabolism.

Inhibition of gastric acid secretion by H_2 antagonists or proton pump inhibitors (PPIs), particularly at high doses, can impair calcium absorption and increase risk of fracture(s) since an acidic environment appears to enhance absorption of some forms of calcium. Furthermore, solubility of calcium is highly pH-dependent, particularly as seen in in vitro experiments. PPIs "also may reduce bone resorption through inhibition of osteoclastic vacuolar proton pumps."[166]

Research

Human studies have shown that cimetidine can lower the amount of calcium in the body, but the conditions, mechanisms, and clinical significance of this interaction pattern are not yet fully understood. Bo-Linn et al.[167] developed a method to measure gastrointestinal absorption of calcium after a single meal. Although a large dose of cimetidine significantly reduced gastric acid secretion, it had no effect on calcium absorption in normal subjects and in one patient with diagnosed achlorhydria. This pattern was observed for all the calcium sources investigated: milk, calcium carbonate ($CaCO_3$), and calcium citrate. Furthermore, calcium absorption from calcium carbonate was the same when intragastric contents were relatively acid (pH 3.0) and when acidity was relatively neutral (pH 7.4). A subsequent trial by Recker[18] found that calcium absorption from calcium carbonate was lower in patients with achlorhydria than in normal subjects. However, when calcium carbonate was taken with a meal, calcium absorption was normal, even in achlorhydric patients. In a review of studies on calcium bioavailability and stomach acid, Wood and Serfaty-Lacrosniere[168] concluded that the elderly, patients taking high doses of gastric acid–suppressive medications, and fasted individuals can most effectively absorb calcium carbonate ingested with a meal. Similarly, Heaney et al.[21] determined that bioavailability of calcium carbonate and calcium phosphate is enhanced when taken with meals.

Ghishan et al.[169] studied the effect of cimetidine on intestinal calcium transport in a rat model and observed a significant decrease in net intestinal calcium transport. In a double-blind, placebo-controlled crossover study, Fisken et al.[170] treated eight primary hyperparathyroid patients with cimetidine or placebo for 2 months and reported that serum calcium levels declined significantly in a single patient and that PTH was affected in only one patient. In a clinical trial involving 16 patients with primary hyperparathyroidism treated with 1200 mg cimetidine daily, Caron et al.[171] proposed that the reduced calcium absorption observed with cimetidine may be secondary to the effects of the drug on vitamin D metabolism rather than inhibition of gastric acid secretion.

Kerzner, O'Connell, et al.[172] conducted a randomized, double-blind, placebo-controlled, crossover trial in which 18 women age 65 and older were administered omeprazole (20 mg daily) or placebo for 7 days, then after a 3-week washout period, switched over to the alternative treatment. On the morning of the seventh day of treatment after an overnight fast, subjects ingested radiolabeled calcium carbonate (500 mg elemental calcium), blood levels of which were measured in samples obtained at time zero and 5 hours later. Each woman also ingested a multivitamin containing 400 units of vitamin D daily throughout the study. The researchers observed that fractional calcium absorption was decreased from an average of 9.1% while treated with placebo to 3.5% with omeprazole. In confirming their hypothesis that omeprazole would alter calcium absorption, the authors added that further trials are needed to "determine whether the body could adapt to this decreased calcium absorption rate and to evaluate other solutions to overcome the omeprazole/proton pump inhibitor–calcium drug-drug interaction."[172] In a nested case-control study comparing users of PPI therapy and nonusers of acid suppression drugs who were over age 50, Yang et al.[166] found that "long-term PPI therapy, particularly at high doses, is associated with an increased risk of hip fracture." Furthermore, use of PPIs for longer than 1 year was associated with increased fracture risk by 44%, and long-term, high-dose users had 2.6 times greater risk than nonusers. However, they added that "short-term PPI use is unlikely to have a significant impact on fracture risk regardless of how high the daily dosage." The authors noted that PPIs "may interfere with calcium absorption through induction of hypochlorhydria but they also may reduce bone resorption through inhibition of osteoclastic vacuolar proton pumps."

Physicians experienced in nutritional therapeutics have often contended that gastric acid secretion declines with age in many individuals, and that this contributes to diminished calcium absorption, cumulative negative calcium balance, and eventually bone loss. In a cross-sectional study involving 248 white male and female volunteers age 65 or older, Hurwitz et al.[173] reported that "nearly 90% of elderly people in this study were able to acidify gastric contents, even in the basal, unstimulated state. Of those who were consistent hyposecretors of acid, most had serum markers of atrophic gastritis." Given the mixed evidence, long-term trials investigating this critical issue are warranted.

The relatively short duration of most trials and the utilization of serum calcium levels as a marker of calcium limit the strength of the available evidence in demonstrating a lack of effect on calcium balance over long periods (i.e., the scale of bone loss).

Report

Edwards et al.[174] reported the case of a 92-year-old woman with a normal serum calcium level who became severely hypocalcemic and exhibited tetany, seizures, and impaired mental status after receiving cimetidine postoperatively. Her condition responded to intravenous diazepam, phenytoin sodium, and parenteral calcium gluconate. Serum calcium levels were maintained by calcium infusions until the cimetidine treatment

was stopped. The authors suggested that the effect of cimetidine on serum PTH level may have been responsible for the observed complications.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing H_2 antagonists, PPIs, or other medications that reduce gastric acidity can advise patients to use calcium preparations other than calcium carbonate, which can be absorbed effectively when taken away from meals. Periodic assessment of calcium levels and BMD would be prudent in patients receiving chronic gastric acid–suppressive therapy, particularly postmenopausal women.

Heparin, Unfractionated

Heparin, unfractionated (Calciparine, Hepalean, Heparin Leo, Minihep Calcium, Minihep, Monoparin Calcium, Monoparin, Multiparin, Pump-Hep, Unihep, Uniparin Calcium, Uniparin Forte).

Interaction Type and Significance

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:	Evidence Base:
4. Plausible or **2. Probable**	◉ **Emerging** or ● **Consensus**

Effect and Mechanism of Action

Over time, heparin causes bone loss, especially in the spine, hips, pelvis, and legs. This effect is more pronounced with standard (unfractionated) heparin (UFH), than with low-molecular-weight heparin (LMWH). At least one mechanism of the negative effect of UFH on bone is nonspecific binding of the longer polysaccharide chains to bone, with inhibition of osteoblastic function. Heparin may also inhibit formation of 1,25-dihydroxyvitamin D by the kidneys.[175]

Research

Majerus et al.[176] reported that use of heparin, at full anticoagulation doses, for several months has been found to cause osteoporosis. Likewise, both Wise and Hall[177] and later Haram et al.,[178] found that women who received heparin therapy during pregnancy experienced decreased bone density, or osteopenia. On the other hand, in one study, nine women undergoing heparin treatment received 6.46 g daily of a special calcium preparation, ossein-hydroxyapatite compound (OHC), over 6 months and were compared to 11 women not receiving the bone-protective treatment. In the OHC-group, good compliance was observed, with no side effects and reduced back pain. Those taking the calcium preparation did not demonstrate the expected decreases in bone mass, whereas bone mass dropped significantly in the controls.[179]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although the adverse effects of heparin on vitamin D, calcium, and bone metabolism are well documented, research confirming the benefits of coadministering calcium and vitamin D in individuals on heparin therapy for any extended period is limited. However, in the meantime, such nutritional support would most likely be beneficial and is not contraindicated. Physicians prescribing UFH may find it prudent to coadminister calcium and vitamin D. With chronic use, the vitamin D metabolite that should be measured to determine vitamin D status is 25(OH)D, which is the major circulating form of vitamin D, circulating at 1000 times the concentration of $1,25(OH)_2D$ and having a half-life of 2 weeks; after D_3 repletion has been initiated, monitoring $1,25(OH)_2D$ may be adequate. With long-term heparin therapy, assessment of BMD may also be indicated.

Isoniazid

Isoniazid (isonicotinic acid hydrazide, INH; Laniazid, Nydrazid); combination drugs: isoniazid and rifampicin (Rifamate, Rimactane); isoniazid, pyrazinamide, and rifampicin (Rifater).

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:	Evidence Base:
2. Probable	◉ **Emerging**

Effect and Mechanism of Action

Isoniazid appears to decrease levels of both calcium and vitamin D and may interfere with the activity of both nutrients. Observed declines in activated vitamin D ($1\alpha,25$-dihydroxyvitamin D) can produce relative hypocalcemia and induce elevation in PTH levels. Isoniazid can inhibit hepatic mixed-function oxidase activity, as evidenced by a reduction in antipyrine and cortisol oxidation, as well as hepatic 25-hydroxylase and renal 1α-hydroxylase; thereby causing such a reduction in the corresponding vitamin D metabolites.[180,181]

Research

Brodie et al.[180] investigated the effect of isoniazid on vitamin D metabolism, serum calcium and phosphate levels, and hepatic monooxygenase activity by administering isoniazid, 300 mg daily, to eight healthy subjects for 14 days. They observed several responses, including a 47% drop in the concentration of $1\alpha,25(OH)_2D$ (most active metabolite of vitamin D) after a single dose of isoniazid, with lowered levels continuing throughout the study, declines in levels of 25(OH)D (major circulating form of the vitamin) in all subjects and to below normal range in six, and a 36% elevation in PTH levels in response to the relative hypocalcemia produced. In a study involving 46 children with asymptomatic tuberculosis (TB), Toppet et al.[182] found that children administered isoniazid for 3 months demonstrated a decrease in blood levels of $1,25(OH)_2D$. Isoniazid appears to interfere similarly with the activity of many other nutrients, including magnesium.

Specific evidence is lacking to determine if isoniazid or related agents actually cause symptoms of vitamin D deficiency and calcium depletion, especially with long-term therapy. Clinical trials are warranted to investigate the clinical significance of any depletion pattern and efficacy of prophylactic intervention. Such research is particularly important in children undergoing long-term therapy, in whom potential adverse effects may significantly impair the calcium economy during the critical life stage when maximum bone density is being attained and will be relied on for a lifetime.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing isoniazid or related antitubercular therapy, especially for greater than 1 month, are advised to recommend coadministration of calcium and vitamin D, preferably as part of a multivitamin-mineral formulation (at least 50 mg/day vitamin B_6 is indicated with INH as well), as a prudent measure, unlikely to interfere with the efficacy of the medication(s). Calcium in the range of 100 to 250 mg three times daily would be appropriate, but research is lacking to confirm specific effective dosage levels. Such nutrient support may be especially critical for children undergoing long-term therapy.

Concurrent vitamin D administration may be of great value in addition to antituberculous drugs in the treatment of tuberculous children, and its use is highly recommended.[183] Exposure to sunlight is the simplest and most natural way to provide activated vitamin D_3; sunshine and mountain air were characteristic of the great TB sanitoriums in the pre–anti-TB drug era. However, when vitamin D is to be administered orally, the typical dosage would be in the range of 5 to 10 µg (200-400 IU) per day, depending on size and body weight.

Granulomatous lesions, such as those present in extensive TB infection, often contain active 1-hydroxylase enzymes that activate 25-OH cholecalciferol and are independent of the feedback mechanisms that regulate the renal 1-hydroxylase enzymes. Regular monitoring of serum calcium would provide indication of early vitamin D toxicity in this setting. Research findings emphasize the need for regular monitoring of vitamin D status in this population, even if no sign of rickets is observed in these patients.

Levothyroxine and Related Thyroid Hormones

L-Triiodothyronine (T_3): Cytomel, liothyronine sodium, liothyronine sodium (synthetic T_3), Triostat (injection).
Levothyroxine (T_4): Eltroxin, Levo-T, Levothroid, levothyroxine (synthetic), levoxin, Levoxyl, Synthroid, thyroxine, Unithroid.
L-Thyroxine and L-triiodothyronine ($T_4 + T_3$): animal levothyroxine/liothyronine, Armour Thyroid, desiccated thyroid, Westhroid.
L-Thyroxine and L-triiodothyronine (synthetic $T_4 + T_3$): Euthroid, Euthyral, liotrix, Thyar, Thyrolar.
Dextrothyroxine (Choloxin).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**
≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**
◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:
5. Improbable

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Calcium compounds may form chelates with levothyroxine or related thyroid medications in the digestive tract, thereby reducing absorption, bioavailability, and efficacy of both agents. In particular, levothyroxine adsorbs to calcium carbonate in an acidic environment.[184] Thyroid hormone medications are known to increase calcium excretion. Most researchers agree that the complete mechanism of this interaction is unknown.

Research

Research on the clinical implications of the binding effect between calcium compounds and thyroid hormone medications is inconclusive, mixed, and contradictory. Several studies have found measurable changes in the bone density of women undergoing long-term treatment with thyroxine and other forms of thyroid medication at substitutive or suppressive doses. Controversy surrounds these findings' interpretation and their implications for bone metabolism. The results of studies examining the influence of T_4 therapy on bone mineral density (BMD) may produce conflicting findings, in part, as a reflection of the inclusion of patients with varying thyroid disorders. Apparently the impact of potential calcium depletion is greatest among women with a history of hyperthyroidism and thyrotoxicosis.

In 1988, Paul et al.[185] cautioned that women treated with L-T_4 for extended periods had a 12.8% lower BMD at the femoral neck and a 10.1% lower BMD at the femoral trochanter compared with matched controls. They suggested that excessive dosages of thyroid hormone might play a significant role in the occurrence of such patterns. In 1991, Adlin et al.[186] noted that long-term L-thyroxine therapy was associated with decreased density of the spine and hip. However, they concluded that because subclinical hyperthyroidism, decreased calcitonin responsiveness, and a history of hyperthyroidism were demonstrated in some or all of these patients, these factors must be considered as possible causes of the decreased BMD. Later in 1991, in a study involving 26 premenopausal women with Hashimoto's thyroiditis receiving long-term physiological doses of levothyroxine replacement therapy, Kung and Pun[187] observed that, compared with controls, women receiving the levothyroxine treatment had normal total-body BMD levels but had significantly lower BMD levels at the femoral neck (−5.7%), femoral trochanter (−7.0%), Ward's triangle (−10.6%), both arms (right, −7.8%; left, −8.9%), and pelvis (−4.9%). In contrast, lumbar spine BMD levels were similar in the two groups. These researchers concluded that patients receiving physiological doses of levothyroxine may have decreased BMD.

However, the findings of other investigators suggest that, under most circumstances, taking thyroid hormones may not be associated with reduced bone density. Franklyn et al.[188] compared case-control studies of patients on long-term T_4 therapy who had or had not previously received radioiodine treatment for thyrotoxicosis, as well as previously thyrotoxic patients who had not required T_4 replacement. After measuring BMD at several sites and comparing results among the three groups, they concluded that thyroxine therapy alone does not represent a significant risk factor for loss of BMD. However, they did note a risk of bone loss in postmenopausal (but not premenopausal) females with a previous history of thyrotoxicosis treated with radioiodine. Thyroid hormone use is much less common in men, who also have less osteoporosis. Schneider et al.[189] compared BMD at several sites in 33 men taking a mean thyroxine-equivalent dose of 130 µg daily, for an average of 15.5 years, with 653 nonusers; all 685 subjects were Caucasian men age 50 to 98. They found no significant differences in BMD at any site between users and nonusers, before or after controlling for age, body mass index, smoking, thiazide diuretics, and oral corticosteroid use. These authors concluded that long-term thyroid hormone use was not associated with adverse effects on BMD in men. Lopez Alvarez et al.[190] determined that histological type of thyroid neoplasia, doses of thyroid hormones, thyroid hormone levels, and duration of follow-up were not associated with changes in BMD.

No published findings among the research reviewed demonstrated the appropriateness or efficacy of calcium supplementation for individuals receiving long-term thyroid therapy.

Systematic research on the effect of calcium supplementation on the absorption of thyroid medication is still in preliminary stages. This probable interaction deserves continued investigation because concurrent treatment with both agents is quite common, particularly in peri- and postmenopausal women. Singh et al.[184] conducted an 8-month prospective cohort study, complemented by an in vitro investigation of T_4 binding to calcium carbonate ($CaCO_3$), and found that simultaneous ingestion of 1200 mg/day calcium carbonate and levothyroxine significantly reduced absorption of the thyroid hormone medication and increased serum thyrotropin levels. Mean levels of both free T_4 and total T_4 were significantly reduced during the calcium period and increased after calcium discontinuation. The in vitro experiment showed that adsorption of T_4 to calcium carbonate occurs at acidic pH levels.[184]

Reports

Schneyer[191] reported reduced levothyroxine effectiveness during simultaneous ingestion of calcium formulations in three women with thyroid cancer who were receiving levothyroxine to suppress serum thyroid-stimulating hormone (TSH) levels. In one case, TSH concentrations increased from 0.08 to 13.3 mU/L over a 5-month period during concomitant administration, and returned to normal after discontinuation of the calcium supplement. Separating the doses of levothyroxine (morning) and calcium carbonate (after lunch or dinner) was reported to minimize the effects of the interaction.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

High calcium intake presents a high probability of interfering with the absorption and activity of thyroid hormone medications if taken simultaneously. Physicians prescribing thyroid therapy should advise patients to take the medication 2 hours before or 4 hours after ingestion of an oral calcium supplement (or calcium-rich foods) to effectively minimize risk of the nutrient interfering with the medication. Many patients find it easiest to take their thyroid medication in the morning and their calcium supplement before bedtime. Thyroid functions should be closely monitored in patients receiving long-term levothyroxine treatment.

No conclusive evidence demonstrates calcium depletion and decreased BMD attributable to thyroid hormone therapy, and no firm evidence supports the proposition that additional calcium supplementation is necessary for or even beneficial to individuals taking thyroid medication on a long-term basis. Even so, many health care providers trained in nutritional therapies have suggested the need for additional calcium supplementation by some patients using these drugs. The seemingly inconsistent findings may indicate that the effect of thyroid medications on calcium varies based on the individual's gender, history, condition, menstrual status, and other factors. Precisely because of this patient variability, many practitioners of nutritional medicine advocate the periodic testing of 24-hour urinary calcium levels for individuals using thyroid medication for more than a few months. Bone densitometry should be performed in patients at risk for osteoporosis. Physicians prescribing thyroid medication should discuss with patients their potential need for calcium supplementation beyond what would normally be recommended based on their age, gender, and menstrual status.

Metformin and Related Biguanides

Evidence: Metformin (Dianben, Glucophage, Glucophage XR).
Extrapolated: Buformin (Andromaco Gliporal, Buformina); metformin combination drugs: glipizide and metformin (Metaglip); glyburide and metformin (Glucovance); phenformin (Debeone, Fenformin).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◇≈≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
2. Probable

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Biguanide therapy, particularly metformin, causes reduced vitamin B_{12} absorption and low serum total vitamin B_{12} and holotranscobalamin (B_{12}-TCII) levels by depressing intrinsic factor secretion[192] and through a calcium-dependent ileal membrane antagonism affecting B_{12}–intrinsic factor complex uptake.[193] Vitamin B_{12}–intrinsic factor complex uptake by ileal cell surface receptors depends on calcium availability, and metformin specifically affects calcium-dependent membrane action; this effect can be reversed by concomitant calcium.

Research

Of patients prescribed metformin, conservatively 10% to 30% have evidence of reduced vitamin B_{12} absorption, accompanied by a decline in folic acid status and elevation of homocysteine (Hcy). An early study by Carpentier et al.[194] involving diabetic patients determined that whereas biguanides depleted vitamin B_{12}, folic acid was not similarly affected. In a subsequent study involving nondiabetic male patients with coronary heart disease, Carlsen et al.[195] observed that metformin increases total serum Hcy levels and depletes vitamin B_{12} and sometimes folic acid.[195] More recently, in a randomized, placebo-controlled trial involving 390 patients with type 2 diabetes, Wulffele et al.[196] found that 16 weeks of treatment with metformin reduces serum levels of vitamin B_{12} and folate, resulting in a modest increase in Hcy.

Caspary et al.[193] initially noted that the vitamin B_{12} malabsorption, pathological Schilling tests, and elevated fecal bile acid excretion observed with biguanides, particularly metformin, improved when the medication was discontinued or antibiotics were administered. They interpreted these findings to suggest that small intestinal bacterial overgrowth, leading to binding of the intrinsic factor–vitamin B_{12}-complex to bacteria, was responsible for the B_{12} depletion observed in diabetic patients on biguanide therapy. Subsequently, Adams et al.[192] surveyed 46 randomly selected diabetic patients on biguanide therapy and found that 30% demonstrated malabsorption of vitamin B_{12}, apparently by two different mechanisms. On withdrawal of the drug, normal absorption returned in only half of those with malabsorption. Using absorption tests with exogenous intrinsic factor, these researchers further determined that

biguanide-induced depression of intrinsic factor secretion mediated the persistent malabsorption in most individuals of the latter group. Bauman et al.[197] performed a comparative study in which a group with type 2 diabetes who had been receiving sulfonylurea therapy was switched to metformin for 3 months, after which oral calcium was administered. Monthly serial measurements of serum total vitamin B_{12} and B_{12}-TCII revealed parallel declines in those taking metformin compared with controls. The observed depression of B_{12}-TCII was reversed by the introduction of oral calcium supplementation.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing metformin or other biguanides are advised to supplement vitamin B_{12}, folic acid, and calcium and regularly monitor folic acid, vitamin B_{12}, and possibly Hcy levels.

Sulfamethoxazole and Related Sulfonamide Antibiotics

Sulfamethoxazole (Gantanol), combination drug: sulfamethoxazole and trimethoprim (cotrimoxazole, co-trimoxazole, SXT, TMP-SMX, TMP-sulfa; Bactrim, Bactrim DS, Cotrim, Septra, Septra DS, Sulfatrim, Uroplus).

Extrapolated, based on similar properties: Sodium sulfacetamide (AK-Sulf, Bleph-10, Sodium Sulamyd), sulfanilamide (AVC), sulfasalazine (salazosulfapyridine, salicylazosulfapyridine, suphasalazine; Apo-Sulfasalazine, Azulfidine, Azulfidine EN-Tabs, PMS-Sulfasalazine, Salazopyrin, Salazopyrin EN-Tabs, SAS), sulfisoxazole (Gantrisin), triple sulfa (Sultrin Triple Sulfa).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability:

4. Plausible or
3. Possible

Evidence Base:

● **Consensus**

Effect and Mechanism of Action

Sulfonamides, including sulfamethoxazole, can decrease absorption of calcium (as well as magnesium and vitamin B_{12}) and potentially lead to calcium depletion.

Research

This interaction is considered as well established, although specific evidence from well-designed clinical trials or qualified case reports is lacking.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The probability of adverse effects on calcium balance is low when medications in the sulfonamide family of antibiotics are used for 2 weeks or less. Physicians prescribing sulfamethoxazole or related medications, especially repeatedly or for longer than 2 weeks, are advised to monitor levels of calcium and other potentially affected nutrients and consider supplementation, such as coadministration of 1000 to 1500 mg calcium in divided doses, at least 2 hours before or after the medication.

Tetracycline Antibiotics

Demeclocycline (Declomycin), doxycycline (Atridox, Doryx, Doxy, Monodox, Periostat, Vibramycin, Vibra-Tabs), minocycline (Dynacin, Minocin, Vectrin), oxytetracycline (Terramycin), tetracycline (Achromycin, Actisite, Sumycin, Tetracyn; combination drugs: chlortetracycline, demeclocycline, and tetracycline (Deteclo); bismuth, metronidazole, and tetracycline (Helidac).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:

2. Probable or
1. Certain

Evidence Base:

● **Consensus**

Effect and Mechanism of Action

Tetracyclines form insoluble chelates with calcium and other polyvalent metal cations, including iron, magnesium, and zinc.[198,199] Thus, calcium and tetracycline-class antibiotics tend to bind with each other, and absorption of both agents is impaired.

Calcium may impair absorption of tetracycline antibiotics and therefore diminish their effectiveness. Tetracycline-class medications are primarily absorbed in the stomach and upper small intestine. Calcium, as well as dairy products and other foods containing high concentrations of calcium, may decrease the absorption of tetracyclines because of chelate formation in the gut.

Tetracyclines reduce absorption of calcium and can adversely affect calcium balance and mineralization of calcium-dependent tissues. The binding of the medication to calcium may also lead to growth retardation and pigmented teeth. Furthermore, tetracycline increases urinary calcium excretion. Thus, with prolonged use, tetracyclines contribute to calcium depletion and can adversely effect bone formation.

Research

Most of the findings leading to statements about this interaction involve calcium-based antacids and calcium-rich foods, but they are still reasonably applicable to calcium supplements. In a review of the effect of polyvalent metallic cations on absorption of tetracyclines, Neuvonen[198] noted that serum concentrations of these antibiotics generally remain within the therapeutic range. Nevertheless, he concluded that "the pharmacokinetic interactions in absorption of tetracyclines likely to be clinically significant in cases where the infecting pathogens are moderately resistant to tetracyclines and relatively high serum concentrations are needed for proper bacteriostasis." In a clinical trial (crossover design) involving 12 healthy volunteers, Jung et al.[200] observed that even a small volume of milk containing extremely small amounts of calcium can severely impair the absorption, and subsequent bioavailability, of tetracycline.

Long-term use of tetracycline antibiotics is highly likely to produce adverse effects on calcium and related tissues and developmental processes. Tetracyclines form a stable calcium complex in any bone-forming tissue. In particular, the interaction between tetracycline and calcium-rich foods (e.g., milk products) exerts adverse effects on bone and teeth that are well documented and widely recognized.[201,202] Unwanted pigmentation and other problems with tooth development caused by tetracycline are well known to dentists and the general public. The tetracyclines also tend to localize in tumors, necrotic or ischemic tissue, liver, and spleen and form

tetracycline-calcium orthophosphate complexes at sites of new bone formation.

Tetracyclines are potent inhibitors of osteoclast function (i.e., antiresorptive). Vernillo and Rifkin[203] describe the processes by which tetracyclines can affect several parameters of osteoclast function and consequently inhibit bone resorption: (1) altering intracellular calcium concentration and interacting with the putative calcium receptor; (2) decreasing ruffled border area; (3) diminishing acid production; (4) diminishing the secretion of lysosomal cysteine proteinases (cathepsins); (5) inducing cell retraction by affecting podosomes; (6) inhibiting osteoclast gelatinase activity; (7) selectively inhibiting osteoclast ontogeny or development; and (8) inducing apoptosis, or programmed cell death, of osteoclasts. For example, a decrease in the fibula growth rate has been observed in premature infants receiving oral tetracycline in doses of 25 mg/kg every 6 hours. This reaction was shown to be reversible when the drug was discontinued.[204]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The mutual impairment of absorption characterizing the interaction between tetracyclines and calcium absorption is highly probable, usually clinically significant, and easily avoided through careful management and instruction. This effect on bone formation carries a significantly greater risk when growth and bone formation is most active, such as with infants and children. Avoiding this interaction is also particularly important in adolescents (e.g., being treated for acne) in the midst of the life stage where they need to attain maximum bone density.

Calcium in the form of antacids, milk products, and supplements should be avoided while using tetracycline-class antibiotics. When continued use of calcium supplements is deemed appropriate and necessary, the calcium supplement (as well as calcium-rich foods) should be taken at least 3 hours apart from ingestion of the medication. Properly managed, separation allows continued effective use of both calcium and the tetracycline antibiotic.

Thiazide Diuretics

Bendroflumethiazide (bendrofluazide; Naturetin); combination drug: bendrofluazide and propranolol (Inderex); benzthiazide (Exna), chlorothiazide (Diuril), chlorthalidone (Hygroton), cyclopenthiazide (Navidrex); combination drug: cyclopenthiazide and oxprenolol hydrochloride (Trasidrex); hydrochlorothiazide (Aquazide, Esidrix, Ezide, Hydrocot, HydroDiuril, Microzide, Oretic); combination drugs: hydrochlorothiazide and amiloride (Moduretic); hydrochlorothiazide and captopril (Acezide, Capto-Co, Captozide, Co-Zidocapt); hydrochlorothiazide and enalapril (Vaseretic); hydrochlorothiazide and lisinopril (Prinzide, Zestoretic); hydrochlorothiazide and losartan (Hyzaar); hydrochlorothiazide and metoprolol (Lopressor HCT); hydrochlorothiazide and spironolactone (Aldactazide); hydrochlorothiazide and triamterene (Dyazide, Maxzide); hydroflumethiazide (Diucardin), methyclothiazide (Enduron), metolazone (Zaroxolyn, Mykrox), polythiazide (Renese), quinethazone (Hydromox), trichlormethiazide (Naqua).

Evidence Base:
◉ **Emerging** or
● **Consensus**

Effect and Mechanism of Action

Thiazide diuretics increase calcium retention by decreasing urinary calcium excretion through their effects on the cortical-diluting segment of the nephron, most likely from the peritubular side.[205-207] Decreased intestinal calcium absorption, suppressed PTH secretion, and inhibited vitamin D synthesis can also result as secondary compensations. Increased renal reabsorption of calcium induced by thiazide diuretics may increase the risk of developing hypercalcemia (and possibly metabolic alkalosis) as a result of concomitant administration of calcium supplements (and/or vitamin D).

Research

Consistent evidence indicates that thiazide-induced decrease in urinary calcium excretion can alter numerous parameters of calcium and vitamin D metabolism and increase risk of transient hypercalcemia, but research has not extended to investigation of potential long-term implications. Leppla et al.[208] conducted a small clinical trial involving seven patients with renal stones to investigate the potential therapeutic role of amiloride in calcium nephrolithiasis. They observed that two doses of amiloride (2.5 mg/day) reduced urinary calcium in two subjects with kidney stones. This decrease in urinary calcium was enhanced in five subjects when amiloride was coadministered with two doses of hydrochlorothiazide (25 mg/day). In a 6-month clinical trial involving six postmenopausal women with osteoporosis, Sakhaee et al.[209] demonstrated that coadministration of hydrochlorothiazide (50 mg/day) and vitamin D (50 µg/day) reduced urinary calcium excretion by 22% but also decreased gastrointestinal calcium absorption by 25%. Riis and Christiansen[206] studied the actions of bendroflumethiazide (5 mg/day), along with 500 mg/day calcium, on vitamin D metabolism in a 12-month placebo-controlled clinical trial in 19 healthy early-postmenopausal women. Subjects in the thiazide group demonstrated a significant elevation in the serum concentration of 24,25-dihydroxycholecalciferol and a tendency toward decreased serum 1,25-dihydroxycholecalciferol, although mean serum 25-hydroxycholecalciferol remained unchanged. The authors noted that all biochemical indices of calcium metabolism were unchanged in the thiazide group, except for a highly significant decrease in urinary calcium.

Some researchers and clinicians have proposed exploiting this interaction between thiazide diuretics and calcium as a potential therapeutic tool in reducing bone loss and preventing osteoporotic fractures. In a 1998 review article, Rejnmark et al.[210] reported that thiazide use is associated with higher BMD, reduced age-related bone loss, and a reduced risk of hip fractures and attributed it not only to decreased calcium excretion, but also possibly to a decrease in PTH-stimulated bone resorption and an associated reduction in the bone turnover rate. However, prudence suggests that such beneficial "side effects" do not provide adequate justification for prescribing this class of medications solely for that purpose, given the other risks associated with their use and the lack of evidence supporting efficacy. Furthermore, the most

relevant evidence indicates that any beneficial effect on calcium in bone metabolism is transient. Thus, in the Rotterdam Study, a prospective population-based cohort study involving 7891 individuals 55 years of age and older, Schoofs et al.[211] reported 281 hip fractures and observed that current use of thiazides for more than 1 year was statistically significantly associated with a lower risk for hip fracture (with no clear dose dependency) compared with nonuse. However, this lower risk disappeared approximately 4 months after thiazide use was discontinued.

Reports

Concomitant use of thiazide diuretics and calcium supplements has been associated with numerous case reports describing hypercalcemia, as well as signs and symptoms of the milk-alkali syndrome, including dizziness, weakness, hypercalcemia, and metabolic alkalosis with respiratory compensation.[212-214] For example, Crowe et al.[215] described a case of symptomatic and reversible hypercalcemia in a 78-year-old female patient taking a combination diuretic (hydrochlorothiazide and amiloride) along with six to eight antacid tablets daily (each containing 680 mg calcium carbonate and 80 mg magnesium carbonate) for several years. Constipation, dehydration, and hypercalcemic alkalosis all resolved when the medications were discontinued during hospitalization. Gora et al.[216] published the case report of a 47-year-old man who was diagnosed with milk-alkali syndrome after being hospitalized with elevated serum calcium (6.8 mEq/L) and serum creatinine (7.2 mg/dL) as well as metabolic alkalosis. During the preceding 2 years he had been self-medicating for dyspepsia with 15 to 20 calcium carbonate tablets daily, each containing 500 mg, while also taking chlorothiazide. His condition improved shortly after this regimen was discontinued.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing thiazide diuretics for treatment of hypertension frequently need to treat such patients concurrently for osteoporosis. In such situations, oral calcium supplements in common dosages do not usually influence blood calcium levels significantly and rarely would impact levels enough to cause clinically significant hypercalciuria.

Thiazides should not be used as a substitute for calcium (and vitamin D) supplementation in the prevention of bone loss and treatment of osteoporosis. Although individuals on long-term thiazide therapy could theoretically reduce calcium intake during such therapy, the available evidence indicates that such beneficial effects do not continue after the thiazide has been discontinued. Evidence is lacking and further research warranted to determine whether any rebound effects on calcium balance or bone loss occurs after thiazide use is suspended, as occurs with some medications.

Given the uncertain implications of the available evidence, physicians are advised to closely supervise and regularly monitor calcium levels when prescribing thiazide diuretics, particularly before initiating or increasing any vitamin D supplementation, and to instruct patients to watch for symptoms of hypercalcemia. In some cases, calcium intake may need to be reduced. When thiazides are indicated, supplementation with potassium and magnesium is usually appropriate to compensate for drug-induced nutrient depletion.

Verapamil and Related Calcium Channel Blockers

Evidence: Felodipine (Plendil), verapamil (Calan, Calan SR, Covera-HS, Isoptin, Isoptin SR, Verelan, Verelan PM). Extrapolated, based on similar properties: Amlodipine (Norvasc); combination drug: amlodipine and benazepril (Lotrel); bepridil (Bapadin, Vascor), diltiazem (Cardizem, Cardizem CD, Cardizem SR, Cartia XT, Dilacor XR, Diltia XT, Tiamate, Tiazac); felodipine combination drugs: felodipine and enalapril (Lexxel); felodipine and ramipril (Triapin); gallopamil (D600), isradipine (DynaCirc, DynaCirc CR), lercanidipine (Zanidip), nicardipine (Cardene, Cardene I.V., Cardene SR), nifedipine (Adalat, Adalat CC, Nifedical XL, Procardia, Procardia XL); combination drug: nifedipine and atenolol (Beta-Adalat, Tenif); nimodipine (Nimotop), nisoldipine (Sular), nitrendipine (Cardif, Nitrepin); verapamil combination drug: trandolapril and verapamil (Tarka).

Effect and Mechanism of Action

Enhanced renal vasoconstriction and renal tubular sodium reabsorption are calcium-dependent functions mediated by noradrenaline and angiotensin II (Ang II) that have been implicated in the pathogenesis of essential hypertension. Calcium supplements (especially in conjunction with high doses of vitamin D) may interfere with the hypotensive activity of and reduce the therapeutic response to verapamil and related calcium channel blockers by increasing calcium availability. Even though the primary activity of these medications involves calcium antagonism, the mechanism of these antagonistic effects on calcium has not yet been fully established. Felodipine use has been associated with increased calcium excretion, and calcium channel blockers may theoretically contribute to increased bone loss. Verapamil may decrease endogenous production of vitamin D and induce target-organ PTH resistance. Nevertheless, calcium administration may reduce adverse effects of calcium channel blockers, and concurrent use of verapamil and intravenous (IV) calcium salts, in particular, can be therapeutically efficacious.

Research

It has been reported that calcium salts may reverse the clinical effects and toxicities associated with verapamil.[217] Weiss et al.[218] found that calcium gluconate, when given as a pretreatment infusion, prevented the fall in blood pressure induced by verapamil, and when administered after verapamil, it restored blood pressure to control values. These researchers also noted that administration of calcium did not alter the antiarrhythmic effect of verapamil. Similarly, in a clinical trial conducted by Haft and Habbab,[219] pretreatment with IV calcium chloride in patients with supraventricular arrhythmias reduced the incidence of hypotensive side effects without compromising the antiarrhythmic effect of verapamil.

Calcium absorption depends on, and calcium function is intertwined with, vitamin D activity. In a 1982 in vitro study, Lerner and Gustafson[220] reported that verapamil

inhibited $1\alpha(OH)_2D_3$-stimulated bone resorption in tissue culture. In an animal model using rats fed a high-calcium diet, Fox and Della-Santina[221] found that chronic oral verapamil administration decreased $1,25(OH)_2D_3$ levels (by reducing production) and increased plasma immunoreactive PTH (most likely by inducing target-organ PTH resistance). In contrast, verapamil produced no significant effect on $1,25(OH)_2D_3$ levels in rats fed a low-calcium diet. A study by Hulthen and Katzman[222] involving 10 patients with essential hypertension found that felodipine use was associated with increased calcium excretion.

Reports

In an isolated report, Bar-Or and Gasiel[223] described a case in which calcium adipate and calciferol antagonized the heart rate–limiting effect of verapamil in a patient being treated for atrial fibrillation.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing verapamil or other calcium channel blockers are advised to exercise caution regarding the concomitant use of calcium (and vitamin D). Concurrent calcium administration in individuals undergoing treatment with calcium channel blockers may be problematic or beneficial, depending on the condition for which the drug has been prescribed, the dosage of calcium intake, and the characteristics of the individual patient being treated. Although of low probability, the potential for an adverse interaction can present strategic concerns because many patients treated with verapamil may also have or be at risk for osteoporosis, such that calcium and vitamin D support is an important concomitant need.

Patient self-administration of calcium should be avoided during treatment with a calcium channel blocker. However, some physicians routinely prescribe very low dosages of calcium, often in the range of 25 to 30 mg per day, for patients who have been diagnosed with angina pectoris or cardiac arrhythmias, but who have no history of hypertension, as a means of reducing excessive and unnecessary blood pressure–lowering activity by the medication. Close supervision and regular monitoring, preferably within the context of integrative care involving health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics, are essential in cases in which concurrent use of verapamil (or a related calcium channel blocker) and calcium (especially with vitamin D) is clinically appropriate. In particular, regular monitoring of blood pressure is required during any coadministration, especially before initiating or significantly changing the level of calcium intake. In cases of overdose with verapamil or other calcium channel blockers, IV calcium chloride or gluconate is the treatment of choice.

UNPROVEN, SPECULATIVE, AND OVERSTATED INTERACTIONS CLAIMS

Albuterol/Salbutamol and Related Beta-2-Adrenoceptor Agonists

Intramuscular (IM), intravenous (IV), and subcutaneous (SC) forms: Albuterol/salbutamol, rimiterol (Pulmadil).
Extrapolated: IM, IV, and SC forms: Fenoterol (Berotec), isoetharine (Arm-A-Med, Bronkosol, Bronkometer), pirbuterol (Exirel), salmeterol, tulobuterol (Brelomax).
Similar properties but evidence indicating no or reduced interaction effects: Inhalation forms: Albuterol (salbutamol; Albuterol Inhaled, Proventil, Ventolin); combination drug: albuterol and ipratropium bromide (Combivent); isoproterenol (isoprenaline; Isuprel, Medihaler-Iso), levalbuterol (Xopenex), metaproterenol (Alupent), salmeterol (Serevent, combination drug: Advair), terbutaline (Brethaire, Brethine, Bricanyl).

Intravenous administration of salbutamol (albuterol) and rimiterol in therapeutic doses produced dose-related decreases in plasma levels of calcium, as well as magnesium, phosphate, and potassium, in four subjects.[224] These researchers advised caution in patients with abnormal glucose tolerance, potassium depletion, or predisposition to lactic acidosis and suggested rimiterol as preferable for infusion because of its short plasma half-life. Further research is warranted to determine if these beta-2-adrenoceptor agonists can induce such adverse effects to a clinically significant degree in individuals being treated for asthma and related conditions over an extended period.

Beclomethasone

Beclomethasone (Beclovent; Beconase; Beconase AQ; QVAR; Vancenase; Vancenase AQ; Vanceril).
Similar properties but evidence indicating no or reduced interaction effects: Other inhaled corticosteroids.

Adverse effects of inhaled corticosteroids are generally presumed to be significantly less than those from oral corticosteroids. However, investigators have reported that most of the beclomethasone from a metered-dose inhaler (MDI) is actually swallowed and can impair calcium absorption. In a 2-week randomized, double-blind, placebo-controlled, crossover trial involving 12 healthy subjects, Smith et al.[121] found that during the period in which they received oral doses of beclomethasone dipropionate (500-µg capsules twice daily), subjects demonstrated a 12% reduction in calcium absorption (measured by strontium absorption test) and a 23% reduction in 24-hour urinary cortisol excretion during the same week. These researchers concluded that decreased calcium absorption resulting from swallowed corticosteroids may contribute to adverse effects of inhaled steroids. Well-designed clinical trials of longer duration are warranted to investigate whether such effects may be a causative factor in long-term bone loss, and whether calcium supplementation or dietary calcium enrichment might be indicated.[226-228]

See also Corticosteroids, Oral.

Caffeine (and Coffee)

Caffeine (Cafcit, Caffedrine, Enerjets, NoDoz, Quick Pep, Snap Back, Stay Alert, Vivarin).
Combination drugs: Acetylsalicylic acid and caffeine (Anacin); acetylsalicylic acid, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); acetylsalicylic acid, codeine, butalbital, and caffeine (Fiorinal); acetominophen, coffee (*Caffea arabica, Caffea canephora, Caffea robusta*), butalbital, and caffeine (Fioricet).

Caffeine is found in coffee, tea, soft drinks, chocolate, guaraná (*Paullinia cupana*), nonprescription over-the-counter (OTC) medications, and supplements containing caffeine or guaraná. For decades, caffeine in general and coffee in particular have been suspected of depleting calcium and contributing to bone loss. Although early studies suggested an epidemiological basis for this conclusion, the evolving picture from continued research has downsized the scope of clinical significance and clarified factors of susceptibility. Caffeine can lead to a small negative calcium balance because of a weak interference with calcium absorption efficiency, particularly in individuals with inadequate calcium intakes.[229] Caffeine can also induce a significant acute calcium diuresis,[224,230] but this renal effect is biphasic[231]; that is, an acute increase in calcium diuresis is

followed by a fall in urinary calcium. Two human trials have found that coffee intake, rather than caffeine, was associated with a negative balance shift of 4 to 6 mg calcium daily for each 100 ml coffee consumed. Conversely, but consistent with the overall pattern, one observational study found accelerated bone loss in 205 healthy postmenopausal women who drank two to three cups of coffee daily and consumed less than 800 mg of calcium daily. Further research is warranted to determine the effects of caffeine in populations characterized by different levels and sources of calcium intake, gender, life stage, bone density, and other potentially influential factors and to compare the variable effects of different sources of caffeine, as well as decaffeinated coffee and differing methods of preparation.

Cisplatin

Cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ).

Cisplatin is nephrotoxic and may cause kidney damage, resulting in depletion of calcium, magnesium, potassium, and phosphate. Calcium supplementation may be appropriate but must be approached with caution and close monitoring, especially in patients with compromised renal function. Strategic integrative protocols, adapted to the particular characteristics and needs of the individual patient, offer expanded possibilities for enhanced care and improved outcomes within the context of collaborative care involving health care professionals trained and experienced in both conventional oncology and nutritional therapeutics.

Colchicine

Colchicine

An isolated case report published by Frayha et al.[232] describes acute colchicine poisoning resulting in symptomatic hypocalcemia in a young female with periodic polyserositis. Experimental data suggest that colchicine-induced hypocalcemia is secondary to colchicine inhibition of bone resorption. Findings from research using a rat model indicate that hypocalcemia may be mediated by interference with the regulatory mechanisms of bone cell calcium homeostasis, and that the destruction of microtubules may be closely related to the development of the hypocalcemia.[233]

Further research may be warranted to determine whether long-term colchicine therapy might contribute to bone loss or other calcium depletion effects, what circumstances or patient characteristics influence susceptibility to a clinically significant interaction, and what nutritional countermeasures might be safe and effective.

Cycloserine

Cycloserine (Seromycin).

Cycloserine may interfere with absorption of calcium and other nutrients, particularly minerals.[234,235] The clinical significance and therapeutic implications of this potential interaction are as yet not understood.

Diclofenac and Related Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Diclofenac potassium (Cataflam), diclofenac sodium (Voltaren).

Related COX-1 inhibitors: Diclofenac combination drug: diclofenac and misoprostol (Arthrotec); diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), furbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen); combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen); indomethacin (indometacin; Indocin, Indocin-SR), ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).

COX-2 inhibitor: Celecoxib (Celebrex).

See also Indomethacin.

Diclofenac can decrease the amount of urinary calcium excretion[236]; it may also inhibit bone resorption in postmenopausal women.[62] Thus, theoretically, coadministration could prevent bone loss in postmenopausal women. Further research is warranted.

Also, in a controlled clinical trial, Miceli-Richard et al.[237] demonstrated that acetaminophen (4 g/day) was not effective in treatment of symptomatic osteoarthritis of the knee.

Digoxin and Related Cardiac Glycosides

Digoxin (Digitek, Lanoxin, Lanoxicaps, purgoxin).

Deslanoside (cedilanin-D), digitoxin (Cystodigin), ouabain (g-strophanthin).

Calcium may interact with digoxin and related agents in two distinct ways. First, the two substances can interact in an additive or possibly synergistic manner. The inotropic action of cardiac glycosides appears to be associated, at least in part, with increased intracellular calcium availability. Chronotropic effects are also mediated by calcium. Thus, high calcium intake (especially by parenteral administration) can produce small increases in plasma calcium, thereby increasing the activity of digoxin and elevating the risk of arrhythmias and other aspects of digoxin toxicity. Second, digoxin also increases renal clearance and could lead to calcium depletion; hypocalcemia can negate the therapeutic activity of digoxin.

Evidence from clinical trials involving digoxin in human subjects, especially cardiac patients, is limited for obvious reasons given the high risk associated with any such experiments. In a 1965 paper, Kupfer and Kosovsky[238] reported that cardiac glycosides can interfere with calcium reabsorption and increase calcium excretion in a dog model through their effect on renal tubular transport of calcium. Although often cited, the clinical significance of this finding has never been established. Sonnenblick et al.[239] compared serum digoxin, calcium, potassium, and magnesium concentrations and arterial pH in 18 patients with gastrointestinal (GI) manifestations of digoxin toxicity with 19 patients with digoxin-induced cardiotoxicity, specifically automaticity. Patients with digoxin-induced GI symptoms had high serum concentrations of the drug. In contrast, those with drug-induced cardiotoxicity (automaticity) had therapeutic concentrations of digoxin but demonstrated higher calcium/potassium ratios and higher pH values.

The concern regarding this interaction dates back to a journal article published more than 70 years ago. In 1936, Bower and Mengle[240] published a "warning" in *JAMA* regarding two fatalities attributed to the "additive effects of calcium and digitalis." Although plausible and frequently cited for decades, no causal relationship was firmly established in these incidents. Techniques for laboratory assessment of digoxin serum levels were unavailable at that time, so it is more likely that the patients had digoxin toxicity and coincidentally were taking calcium. Other case reports describe cardiac arrhythmias associated with concomitant administration of cardiac glycosides and calcium preparations, primarily involving IV administration.[241]

In consideration of the drug's narrow therapeutic range, physicians prescribing digoxin and related cardioactive agents should advise patients to maintain stable calcium intake. Prudence suggests that blood calcium levels be monitored closely when significant or rapid changes in calcium status or intake are anticipated or undertaken. Calcium supplementation may be appropriate if deficiency is indicated, but any change in intake should be gradual and supervised closely. In most cases, checking serum calcium at onset of digoxin therapy is probably adequate. After that, monitoring digoxin level is probably the most important test. Hypocalcemia or hypercalcemia can clearly be problematic with digoxin therapy but generally is not caused by calcium supplements or their absence.

Although calcium status plays a significant role in the efficacy and safety of digoxin, supplemental or dietary calcium intake is unlikely to interact with digoxin to a clinically significant degree in most cases. Hypercalcemia increases digoxin toxicity, and hypocalcemia reduces digoxin's therapeutic effect. However, oral calcium supplements in common dosages do not usually influence blood levels of calcium levels to a significant degree and rarely would impact blood levels of calcium enough to cause a clinically significant interaction with digoxin. In absence of calcium deficiency, mimimal calcium is absorbed from the gut. In a deficiency state, calcium is mobilized from bone, through increased parathyroid hormone (PTH) secretion, to maintain the blood levels. Thus, under normal conditions, calcium homeostasis regulates blood calcium levels within a range unlikely to destabilize a patient taking digoxin.

Ionized calcium, normally tightly regulated by vitamin D, calcitonin, and PTH, would much more likely be problematic than calcium intake. Intravenous calcium carries a significant risk for an adverse interaction. Physicians administering parenteral or IV calcium to individuals undergoing digoxin therapy will presumably be closely monitoring such patients and working within a setting suitable to providing the necessary responses to unstable situations or unexpected developments. Low potassium and magnesium also increase digoxin toxicity.

Dobutamine

Dobutamine (Dobutrex).

Human research indicates that IV administration of calcium chloride may diminish the therapeutic effect of dobutamine, specifically its cardiac-stimulating properties.

In a clinical trial involving 22 patients administered dobutamine after coronary bypass surgery, Butterworth et al.[242] observed a 30% reduction in cardiac output with concomitant administration of calcium chloride by continuous infusion. These subjects had a normal cardiac output before calcium administration. In contrast, milrinone was not affected by the calcium administration. The authors could not demonstrate the mechanism involved in this interaction but suggested that calcium may interfere with signal transduction through the beta-adrenergic receptor complex.

Physicians administering dobutamine are advised to monitor for decreased cardiac output or other reduction of therapeutic effects if exogenous calcium is administered or the dose increased, especially intravenously. Evidence is lacking to support any extrapolation of this finding to oral calcium supplementation.

Erythromycin and Related Macrolide Antibiotics

Azithromycin (Zithromax), clarithromycin (Biaxin), dirithromycin (Dynabac), erythromycin, oral (EES, EryPed, Ery-Tab, PCE Dispertab, Pediazole), troleandomycin (Tao).

Erythromycin may interfere with the absorption and activity of calcium and other nutrients. Although not usually clinically significant with short-term administration, the increased risk of calcium depletion can become a concern with extended use. Further research is warranted to investigate potential adverse effects on calcium balance and bone metabolism with extended macrolide therapy.

Physicians prescribing erythromycin and related macrolide antibiotics internally for longer than 2 weeks are advised to supplement calcium (as well as folic acid, vitamins B_6 and B_2, and magnesium) as a preventive measure, with separation of oral intake. Any potential drug-induced adverse effect on bone formation would carry a significantly greater risk when growth and bone formation are most active, such as with infants and children. Avoiding such an interaction would also be particularly important in adolescents (e.g., being treated for acne) in the midst of the life stage where they need to attain maximum bone density.

Hydroxychloroquine and Chloroquine

Hydroxychloroquine (Plaquenil).
Related: Chloroquine (Aralen, Aralen HCl).

Preliminary data suggest that hydroxychloroquine might induce hypocalcemia or calcium depletion. An isolated case report described the use of hydroxychloroquine to block the formation of active vitamin D and normalize elevated blood levels of calcium in a 45-year-old woman with sarcoidosis.[243] Evidence is lacking to confirm or disprove such effects of hydroxychloroquine administration in individuals not presenting with sarcoidosis or elevated calcium. Pending further research with well-designed clinical trials, physicians prescribing hydroxychloroquine are advised to monitor vitamin 25(OH)D and calcium status.

Indapamide

Indapamide (Lozol).

As a thiazide-like diuretic, indapamide carries a high probability of interacting with nutrients in a manner similar to interactions observed with thiazide diuretics. Thus, preliminary data suggest that indapamide may cause slight elevation in blood calcium levels, and that concomitant administration of calcium supplements could potentially aggravate this risk.[244-247] Physicians prescribing indapamide should monitor blood calcium levels and consider whether calcium supplementation is contraindicated for the individual being treated.

Indomethacin

Indomethacin (Indometacin; Indocin, Indocin-SR).

Prostaglandins E_1 and E_2 (PGE_2) stimulate bone resorption. This has been proposed as a possible mechanism for hypercalcemia in malignancy (particularly renal cell carcinoma). Some in vitro and in vivo research has shown that indomethacin, a specific prostaglandin biosynthesis inhibitor, may reduce plasma calcium (and phosphate) levels. However, in a trial involving patients with breast cancer, Coombes et al.[248] found that indomethacin did not reduce serum calcium levels in patients with hypercalcemia, nor did it reduce skeletal destruction, as measured by the urinary hydroxyproline/creatinine ratio and urinary calcium in normocalcemic or hypercalcemic patients with osteolytic metastases. Similarly, in a study of PGE_2, parathormone (PTH), and response to indomethacin in patients with hypercalcemia of malignancy, Brenner et al.[249] found that PGE_2 and calcium fell to normal levels in 3 of 14 patients (breast, colon, renal carcinomas) after

administration of indomethacin. In a rat model, Gomaa et al.[250] observed that indomethacin increased serum levels of calcium.

This potential interaction could be especially relevant in patients using indomethacin for joint pain and inflammation (e.g., osteoarthritis) or after orthopedic procedures. However, evidence is lacking to determine whether coadministration of nutrients might be appropriate or beneficial.

Laxatives, Stimulant

Laxatives, Stimulant

Stimulant laxatives may reduce absorption of calcium from dietary or supplemental sources.[251] With prolonged use, this action could result in adverse effects. Physicians are generally advised to inform patients to limit the duration of stimulant laxatives for many reasons, including potential for decreased absorption and potential depletion of key nutrients, including calcium.

Loop Diuretics

Bumetanide (Bumex), ethacrynic acid (Edecrin), furosemide (Lasix), torsemide (Demadex).

Loop diuretics act in the luminal side of the ascending part of the kidney's diluting segment and will increase the urinary excretion of calcium, subsequently increasing blood calcium levels.[252] This action could theoretically induce osteopenia; it may also increase the risk of calcium oxalate stones.

The available data from clinical research suggest that loop diuretics can alter calcium levels but are inadequate for determining whether and under what conditions such interaction may be clinically significant. In a trial involving 16 healthy volunteers treated with bumetanide, Davies et al.[253] found that the effects on calcium may be relatively less pronounced with this medication than with other drugs in this class; urinary calcium loss was initially elevated but was followed by retention at 24 hours (0.25–1.0 mg orally). Ogawa et al.[254] observed that furosemide (40 mg) caused marked calciuresis but also elevated serum calcium levels in an experiment involving five healthy male subjects. The authors noted that the effects of increased calcium excretion "may not extend to bone calcium remodeling at least in such a short-term experiment."

Fujita et al.[255] examined the effects of short-term administration of furosemide (4–7 days) on the response to exogenous parathyroid extract in six normal subjects. All six subjects demonstrated marked increases in urinary calcium excretion, reduced serum ionized calcium levels, and significant increase in urinary cyclic adenosine monophosphate (cAMP) from the control to the furosemide periods. Further research with well-designed clinical trials is warranted to clarify the clinical effects of loop diuretics on calcium metabolism and homeostasis and to determine guidelines for a safe, effective clinical response.

Physicians prescribing loop diuretics should advise patients to discuss their status, and/or consult with a health care professional trained and experienced in nutritional therapies, before initiating or increasing their level of calcium supplementation. Despite a lack of evidence establishing a general need for calcium support, increased calcium intake through diet or supplements may be appropriate during loop diuretic therapy in some individuals at high risk for bone loss. However, in patients taking both loop diuretics (especially furosemide) and calcium supplementation, testing of 24-hour urinary calcium levels may be prudent in patients with increased risk of calcium oxalate stones. Choosing which form of calcium to use may be significant in supporting bone density while minimizing risk of nephrolithiasis.

Medroxyprogesterone

Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); medroxyprogesterone, injection (Depo-Provera, Depo-subQ Provera 104); medroxyprogesterone, oral (Cycrin, Provera).

The evidence is mixed and preliminary, but the available data indicate that medroxyprogesterone administration probably increases bone loss, even with calcium coadministration. Hergenroeder et al.[256] conducted a randomized, controlled clinical trial involving 24 Caucasian women, age 14 to 28, with hypothalamic amenorrhea or oligomenorrhea, comparing the effects of treatment using oral contraceptives (OCs), medroxyprogesterone, or placebo over 12 months. Measuring bone mass at 6 and 12 months, they found that spine and total-body bone mineral measurements in amenorrheic subjects at 12 months were greater in the OC group than in the medroxyprogesterone and placebo groups, and that no detectable improvement in bone mineral associated with medroxyprogesterone use in oligomenorrheic subjects. There were no measurable differences in hip bone mineral calcium and bone mineral density (BMD) measurements at 12 months among the three groups. Merki-Feld et al.[257] conducted a 2-year prospective study on the effects of depot medroxyprogesterone acetate (DMPA) on bone mass response to estrogen and calcium therapy in women age 30 to 45. In particular, their investigation focused on the effects of estrogen or calcium substitution during the second year of follow-up in seven DMPA users with a high annual bone loss during the first year. The baseline cortical and trabecular bone mass (TBM) and the annual change was no different in DMPA users and controls. Over 24 months the researchers measured an increase in TBM of 0.6% and a decrease in cortical bone mass of 0.1% in exposed women. Some (but not all) DMPA users with bone loss during the first year could be successfully treated with estradiol or calcium. These authors concluded that no significantly accelerated bone loss was associated with DMPA use in women 30 to 45 years of age.

Berenson et al.[258] compared the effects of 24 months of DMPA on lumbar spine BMD compared with self-selected oral contraconception (pills) and nonhormonal contraception (controls) in 191 women age 18 to 33. They observed that women using DMPA for 24 months demonstrated on average a 5.7% loss in BMD, with a 3.2% loss occurring between months 12 and 24. In contrast, users of desogestrel pills experienced an average 2.6% loss in BMD after 24 months. These authors concluded that DMPA appeared to be associated with linear pattern of decreased BMD during the first 2 years of use.

Calcium nutriture and weight-bearing exercise form the foundation of bone health in women during the menstrual years. Physicians prescribing medroxyprogesterone will want to remind patients of the basic preventive needs and suggest that consistency may be especially important given the potential for increased bone loss under the influence of this form of contraceptive.

Mineral Oil

Mineral Oil (Agoral, Kondremul Plain, Milkinol, Neo-Cultol, Petrogalar Plain).

Mineral oil, as a lipid solvent, may absorb many substances and interfere with normal absorption of calcium and other nutrients.[259] The effect of mineral oil on fat-soluble nutrients such as vitamin D, which is essential to calcium absorption, can further adversely influence calcium bioavailability. Although

some research suggests that these interactions may be clinically significant, especially with long-term administration and simultaneous intake, the collective evidence is mixed and inconclusive.

Health care professionals advising patients using mineral oil for any extended time can recommend regular use of a multivitamin-mineral supplement as potentially beneficial. Administering mineral oil on an empty stomach or ingesting vitamin/mineral supplements at least 2 hours before or after the mineral oil can effectively minimize malabsorption of fat-soluble nutrients. However, in general, the internal use of mineral oil should be limited to less than 1 week.

Potassium-Sparing Diuretics

Amiloride (Midamor), spironolactone (Aldactone), triamterene (Dyrenium); combination drugs: amiloride and hydrochlorothiazide (Moduretic); spironolactone and hydrochlorothiazide (Aldactazide); triamterene and hydrochlorothiazide (Dyazide, Maxzide).

Potassium-sparing diuretics can increase calcium loss through urinary excretion, but evidence is lacking to determine whether and under what circumstances this effect might lead to a clinically significant pattern of calcium depletion.[260-262] Reduced calcium loss has also been posited, similar to that found with thiazide diuretics.

Leppla et al.[208] conducted a small clinical trial involving seven patients with renal stones to investigate the potential therapeutic role of amiloride in calcium nephrolithiasis. They observed that two doses of amiloride (2.5 mg/day) reduced urinary calcium in two subjects with kidney stones. This decrease in urinary calcium was enhanced in five subjects when amiloride was coadministered with two doses of hydrochlorothiazide (25 mg/day). The clinical implications of this observed effect on calcium metabolism are unclear at this time.

Triamterene may increase urinary calcium excretion. However, the clinical implications of this possible interaction are limited.

The evidence regarding this interaction is inconsistent and has yet to mature. Nevertheless, physicians prescribing potassium-sparing diuretics are advised to be aware of potential alterations in calcium status caused by these agents and to consider calcium supplementation or contraindication, as indicated by the individual patient's age, gender, medical history, BMD, and other relevant factors.

Retinoic Acid and Related Retinoids

Acitretin (Soriatane), bexarotene (Targretin), etretinate (Tegison), isotretinoin (13-*cis* retinoic acid; Accutane), tretinoin (All-Trans-Retinoic Acid, ATRA, Atragen, Avita, Renova, Retin-A, Vesanoid, Vitinoin).

Long-term or high-dose administration of vitamin A derivatives (retinoids) may produce a variety of skeletal adverse effects in humans. Kindmark et al.[263] investigated the early effects of oral isotretinoin therapy on bone turnover and calcium homeostasis in 11 consecutive patients with nodulocystic acne. They reported that markers of bone turnover and urine levels of calcium and hydroxyproline decreased significantly within 5 days of treatment. There was also a statistically significant decrease in serum calcium, with a minimum on day 5, and a marked increase in serum PTH. However, with continued treatment, the abnormal levels of these markers returned to baseline values within 14 days. Further research with well-designed clinical trials is warranted to investigate long-term implications of retinoic acid therapy on calcium economy and bone health.

Physicians prescribing retinoic acid or related retinoid therapies internally for longer than 2 weeks are advised to supplement calcium (300 mg three times daily) as a preventive measure.

Salicylates

Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab).

Experimental data indicate that salicylic acid analogs with the carboxyl group adjacent to the hydroxyl group on the benzene ring can induce hypocalcemia. Kato et al.[264] found that orally administered aspirin and sodium salt of *o*-hydroxybenzoic acid (Na-salicylate), but not the sodium salt of *m*- and *p*-hydroxybenzoic acid (HBA), induced hypocalcemia; 2,5-dihydroxybenzoic acid (DHBA) and PAS sodium dihydrate (PAS-Na) caused hypocalcemia when administered intravenously but not orally. Related findings from IV injection of aspirin–dl-lysine (water-soluble aspirin) and SA–dl-lysine suggest that prostaglandins are not involved in the process of aspirin-induced hypocalcemia in the rat.[264]

Further research involving well-designed clinical trials is warranted to assess the short-term effects and long-term clinical implications of this potential interaction between salicylates and calcium, particularly in regard to long-term bone loss, joint pain, osteoarthritis, and analgesic use.

Sodium Fluoride

Sodium fluoride (Fluorigard, Fluorinse, Fluoritab, Fluorodex, Flura-Drops, Flura-Tab, Karidium, Luride, Pediaflor, PreviDent).

Calcium may reduce absorption of fluoride, and vice versa, when taken simultaneously.[265]

In a review article, Deal[266] reported that fluoride monotherapy can transfer calcium from leg bones to the spine, thus increasing the risk of stress fractures. However, coadministration of 1500 mg calcium daily and slow-release forms of fluoride increases the lumbar spine BMD without causing fractures.

Haguenauer et al.[267] conducted a meta-analysis of randomized controlled trials investigating efficacy of fluoride therapy on bone loss, vertebral and nonvertebral fractures, and adverse effects in postmenopausal women. Although fluoride therapy demonstrates an ability to increase lumbar spine BMD, it does not result in a reduction in vertebral fractures. Further, increasing fluoride dose raises the risk of nonvertebral fractures and incidence of GI adverse effects without providing any beneficial effect on the vertebral fracture rate. Health care

professionals experienced in nutritional therapies report that sodium fluoride, when used as a treatment for osteoporosis, does harden bone, but it also renders bone less elastic and more brittle, and increases fracture risk. Further research is warranted to investigate this clinically important interaction and develop therapeutic guidelines integrating calcium supplementation and other nutritional interventions into a comprehensive strategy for treating osteoporosis that mitigates adverse effects and maximizes the therapeutic benefits of sodium fluoride therapy on bone quality.

Physicians prescribing fluoride to enhance bone mass are advised to coadminister calcium (400-500 mg three times daily) but to separate oral ingestion by at least 2 hours to reduce the risk of the two agents interfering with each other's absorption. Weight-bearing exercise, vitamin D, and sunlight exposure are also advisable to support bone health and reduce risk of bone loss.

Sucralfate

Sucralfate (Carafate).

Vucelic et al.[268] conducted a clinical trial investigating the effects of sucralfate on serum phosphorus, calcium, and alkaline phosphatase in 30 patients with chronic renal failure on intermittent hemodialysis. They reported an increase in serum calcium (as well as a significant reduction in serum phosphorus and alkaline phosphatase) after 14 days of treatment with sucralfate (1 g four times daily).

Calcium administration requires supervision during sucralfate therapy for hyperphosphatemia and secondary hyperparathyroidism in patients with chronic renal failure; avoidance of calcium may be appropriate in some cases. Physicians prescribing sucralfate should monitor patients for signs of hypercalcemia, which might be induced or aggravated by high calcium intake. Furthermore, serum phosphorus should be checked routinely in patients treated with sucralfate for peptic ulcer disease, although the risk of interference in calcium-phosphorus homeostasis is certainly much lower in patients with normal renal function. In the absence of clinical trial data, clinical vigilance is warranted.

Tamoxifen

Tamoxifen (Nolvadex).

Tamoxifen preserves BMD in postmenopausal women but may increase bone loss in premenopausal women.[269] Hypercalcemia is a rare adverse effect associated with tamoxifen therapy, the risk of which could theoretically be increased by calcium supplements. Hypercalcemia can occur in any advanced cancer in which the tumor cells make parathyroid-related protein (a peptide hormone), and in such tumors, concomitant calcium could aggravate the condition. However, the only time tamoxifen causes hypercalcemia is in breast cancer patients with bone metastases, who have a "tamoxifen tumor flare" in the first 2 to 3 weeks after initiating tamoxifen therapy; this is caused by the estrogen agonist activity of tamoxifen being asserted before the estrogen antagonist effect takes hold. Tumor flare is well known to be highly predictive of an ultimate therapeutic response in the breast cancer patient. Calcium intake during this brief window of tumor flare might exacerbate the hypercalcemia, but bone (rather than oral intake of calcium) is the primary source of the calcium in such cases. These patients respond to bisphosphonates, such as pamidronate and related drugs, which increase the binding of calcium to the bone matrix and shut down the function of osteoclasts, which are necessary to mobilize calcium from bone.

Calcium supplementation may be appropriate outside this volatile initial phase but must be approached with caution and close monitoring. In the longer term, physicians prescribing tamoxifen for prevention or treatment of breast cancer can enhance the bone health of these patients by recommending adequate calcium and vitamin D intake through dietary and supplemental sources (at appropriate phases in the therapeutic process), encouraging weight-bearing exercise and sunlight exposure and counseling about the relationship between smoking and alcohol and bone loss. Together these prudent recommendations will support overall health and may lessen bone loss and the risk of subsequent osteoporosis. BMD should be measured in women receiving chemotherapy of any type. Strategic integrative protocols, adapted to the characteristics and needs of the individual patient, offer expanded possibilities for enhanced care and improved outcomes within the context of collaborative care involving health care professionals trained and experienced in both conventional oncology and nutritional therapeutics.

NUTRIENT-NUTRIENT INTERACTIONS

Alcohol

Excessive alcohol intake may reduce calcium absorption.

Caffeine and Coffee

See Caffeine.

Essential Fatty Acids

Omega-6 fatty acids: Gamma-linolenic acid.
Omega-3 fatty acids: Alpha-linolenic acid (ALA), docosahexaenoic acid (DHA), eicosapentaenoic acid (EPA).

Animal studies and some evidence from human research indicate that essential fatty acids (EFAS) may enhance calcium absorption, at least in part, by enhancing the effects of vitamin D, to reduce urinary calcium excretion, to increase calcium deposition in bone and improve bone strength, and to enhance bone collagen synthesis.[270-272] Animals deficient in EFAs develop severe osteoporosis with increased renal and arterial calcification. In particular, these effects from the interaction between EFAs and calcium metabolism are associated with reduced ectopic calcification, specifically in the arteries and the kidneys, a major factor in mortality associated with osteoporosis.

In a randomized clinical trial involving 65 postmenopausal women taking a background diet low in calcium, Kruger et al.[272] observed that the coadministration of gamma-linolenic acid (omega-6 fatty acids from evening primrose oil) and eicosapentaenoic acid (omega-3 fatty acids from fish oil) with 600 mg/day calcium carbonate for 18 months was associated with improvements in markers of bone formation/degradation and bone mineral density (BMD), as well as a decreased incidence of fractures. In contrast, Bassey et al.[273] found no significant benefit in two randomized controlled trials comparing effects of calcium-EFA combination versus calcium alone on BMD in healthy premenopausal and postmenopausal women. The apparent inconsistency between these findings may reflect differences in the ages, general health status, diet, physical activity level, and other influential factors, which were significantly contrasting in the groups of women studied and need to be taken into account in any comparison between the studies and their results. In particular, long-term activity level and nutritional status, especially long-term dietary intake of calcium and EFAs, are known to affect calcium absorption and bone health.

Both calcium and EFAs have beneficial effects on the population with or at risk for osteoporosis. However, further research is warranted to investigate the specific interaction(s) between calcium and EFAs, as well as the mechanisms of action, clinical significance, and therapeutic implications for bone health and other functions and conditions.

Iron

Concomitant administration of calcium and iron can decrease GI absorption of iron, particularly from nonheme sources.[274] Calcium supplements inhibit absorption of supplemental iron to a greater degree when taken with food.[275,276] Evidence, some extrapolated from research involving antacids, suggests that calcium can interfere with the absorption of iron and possibly other minerals by neutralizing stomach acid.[148,277] However, human research indicates that clinically significant effects on the status of either mineral are improbable, most likely because of compensatory changes in absorption rates.[278] Thus, it is unlikely that iron absorption is significantly reduced when iron and calcium are combined within a multimineral formulation. Nevertheless, when iron and calcium are being taken as separate supplements, separation of intake by 2 or more hours will avoid any impairment of absorption. Furthermore, taking calcium supplements away from meals appears to reduce adverse effects on absorption of iron and possibly other nutrients.

Lysine

Animal and human studies demonstrate that lysine can enhance intestinal calcium absorption and improve the renal conservation of the absorbed calcium, thus reducing urinary calcium excretion.[279,280] Coadministration of calcium and L-lysine supplements may provide a synergistic benefit for both preventive and therapeutic interventions in osteoporosis. Further research with well-designed, long-term clinical trials is warranted.

Magnesium

Magnesium intake from food and supplements is associated with BMD.[281] Concomitant administration of calcium and magnesium, particularly with high calcium intake, decreases GI absorption of magnesium. However, such competition does not appear to exert clinically significant effects on status of either mineral.[282-284]

Calcium supplementation, as well as cessation of magnesium administration, is typically used in treating hypermagnesemia.

Milk and Dairy Products

Cow's milk contains a different proportion of various mineral constituents than human milk. In particular, cow's milk, dairy products, and other foods that are high in phosphorus may reduce calcium absorption by forming insoluble complexes with calcium ions. Lactose does not enhance calcium availability in lactose-tolerant individuals.[285] Controversy continues as to whether calcium in many dairy products (1) may have limited bioavailability for individuals who do not properly digest dairy products because they lack sufficient lactase to digest the milk sugar or (2) may react to the characteristic proteins.

Phosphorus

Oral administration of calcium, as a divalent cation, may bind with oral phosphate and interfere with phosphorus absorption in the GI tract.[271,286] Most commentators portray the adverse impact of high phosphorus intake (e.g., in phosphoric acid—containing soft drinks, particularly in association with cola) on calcium function as the more clinically significant adverse effect of this interaction. Nevertheless, contentious debate and unresolved issues characterize the literature concerning the interactions, mechanisms, contextual influences, and clinical implications of high phosphorus intakes on calcium balance and bone health, as well as the impact of calcium on phosphorus balance.

Higher phosphorus intake has been associated with slightly lower levels of urinary calcium but also with slightly increased intestinal secretion of calcium, resulting in increased calcium loss in the feces.[287] Overall, the increase in endogenous fecal calcium from increasing phosphorus is generally about equal to the effect from decreasing urinary calcium. Diets high in phosphorus and low in calcium have been found to increase PTH secretion.

In terms of dietary consumption patterns, phosphorus intake tends to displace calcium intake. Animal protein, dairy products, and many carbonated beverages are especially high in phosphorus. The use of phosphorus-containing food additives contributes substantially to daily phosphorus intake for most people consuming a standard American diet, and their use is increasing, especially in processed foods. In particular, soft drinks often contain phosphoric acid as an acidulant to maintain carbonation, and the link between consumption of soft drinks and bone loss has been the subject of much discussion. Dietary intervention studies have shown that elevations in serum phosphorus resulting from high phosphorus intake may have physiological consequences that are harmful to both bone and kidney when sustained over time and particularly when calcium intake is low. Intake of foods rich in phosphorus (especially as additives) and low in calcium is associated with a persistent elevation in serum PTH levels but no increase in calcitriol ($1,25\text{-}OH_2D$, the active metabolite of vitamin D).[288] Such dietary patterns among children and adolescents do not bode well for long-term risk of osteoporosis in populations eating a standard American diet.[289]

One stream of research indicates that calcium intake, especially at relatively high levels, may adversely affect phosphorous balance. Thus, Heaney and Recker[228] concluded that no net association of different phosphorus intakes with calcium balance was likely because these two effects were opposite in direction. Twenty years later, Heaney and Nordin[290] led a team of researchers investigating the impact of high calcium intake on phosphorus absorption, metabolism, and function. They observed that phosphorus absorption falls and the risk of phosphorus insufficiency rises when calcium intake increases without a corresponding increase in phosphorus intake. In particular, they expressed a concern for dietary intakes with high Ca:P ratios that can occur with use of calcium supplements or food fortificants consisting of nonphosphate calcium salts. These researchers concluded that "older patients with osteoporosis treated with current generation bone active agents should receive at least some of their calcium co-therapy in the form of a calcium phosphate preparation."[290]

Health care professionals concerned with bone health and the unresolved complexities of the interaction between these two important nutrients can most benefit their patients by strongly advocating an active lifestyle supported by a diverse and balanced diet of fresh, nutrient-rich foods and minimal intake of processed foods and soft drinks throughout life, but especially during those life stages emphasizing attainment of maximal bone density and prevention of bone loss. Use of

a multimineral formulations containing phosphorus has been recommended for individuals, especially the elderly, regularly taking high doses of calcium. In general, separating intake of supplemental phosphorus from calcium intake, either as calcium-rich foods or supplements, by at least 2 hours will minimize any impairment of absorption of either nutrient.

Protein

The effect of dietary protein on calcium balance is often treated as if it were a well-documented phenomenon, but it still remains contentious, seemingly paradoxical, and ultimately unresolved. Increases in dietary protein intake are directly associated with increased urinary calcium excretion and increased risk of bone loss over time. As the intake of dietary protein increases, the urinary excretion of calcium increases as a result of decreased fractional tubular reabsorption, such that doubling protein intake results in a 50% increase in urinary calcium excretion.[287] Using data from Zemel,[291] Weaver et al.[292] calculated that each additional gram of protein consumed results in an additional loss of 1.75 mg of calcium per day. Given an average absorption efficiency of 30% for dietary calcium, each 1-g increase in protein intake per day creates a requirement for an additional 5.8 mg of calcium per day to offset the protein-induced calcium loss.

Lifelong high intake of dietary animal protein correlates with increased risk of osteoporosis in most studies.[293] After sustaining an osteoporotic fracture, however, a 20-g/day supplement of protein reduced bone loss compared with similar patients not supplemented with protein.[294] Another randomized, double-blind trial showed that a supplement of soy protein powder providing 40 g protein and 90 mg soy isoflavones increased BMD at the spine in postmenopausal women.[295]

The effect of high protein on bone health remains unclear and controversial. The seemingly inconsistent findings could easily reflect differences in subject characteristics, medical conditions, materials tested, and dosage levels more than they reveal fundamental contradictions. Nevertheless, advising calcium supplementation along with increased dietary protein is probably reasonable. Diets simultaneously high in protein and inadequate in calcium especially may put people at risk for skeletal sequelae, particularly in later life. Furthermore, even though a large proportion of those consuming a standard American diet are more likely at risk of excess protein effects on calcium economy, those with insufficient protein intake are at perhaps greater risk of poor bone health. In particular, serum albumin levels (paralleling protein nutriture) are inversely related to hip fracture risk, and inadequate protein intakes have been associated with poor recovery from osteoporotic fractures.[289]

Sodium

The available evidence suggests that high sodium intake is associated with adverse effects on calcium and increased risk of bone loss. Increased sodium intake results in increased urinary calcium excretion, possibly because of competition between sodium and calcium for reabsorption in the kidney or through an effect of sodium on PTH secretion.[288,292,296] In a 2-year longitudinal study of the effect of sodium and calcium intakes on regional bone density in 124 postmenopausal women, Devine et al.[297] found that increased urinary sodium excretion (indicative of increased sodium intake) was associated with decreased BMD at the hip. Further research into this important interaction is clearly warranted, particularly given the strong association between diets high in sodium and decreased intake of foods rich in calcium and other beneficial nutrients.[289]

Soy

Phytic acid can interfere with the absorption of calcium. However, some research shows that soy products have relatively high calcium bioavailability, even though soybeans are rich in both oxalate and phytate.[292] Some health care professionals recommend a 2-hour separation between intake of calcium supplements and eating soya products.

Vitamin D

See also earlier Strategic Considerations discussion.

Coadministration of vitamin D and calcium, along with weight-bearing exercise and sunlight exposure, are generally considered the foundational approaches to calcium nourishment, attainment and maintenance of BMD, and prevention of bone loss.[298-300] A normal physiological function of vitamin D is to facilitate intestinal calcium absorption.

Although findings have varied, often significantly influenced by methodology (especially in meta-analyses), most research indicates that concomitant intake of calcium and vitamin D reduces risk of fractures and enhances bone health, particularly with individuals with a preexisting insufficiency and consistent patient compliance. In general, according to Heaney and Weaver,[79] prudent nutritional support for osteoporosis prevention and treatment consists of 30 to 40 mmol calcium daily with sufficient vitamin D to maintain serum 25(OH)D levels above 80 nmol/L (~25 µg [1000 IU] vitamin D/day). In a Cochrane Library review of 38 randomized or quasi-randomized trials, Avenell and Handoll[301] found that the risk of fractures of the hip and other nonspinal bones was reduced slightly in elderly people who are frail and at risk for bone fractures, particularly those who live in nursing homes or other institutions, if vitamin D and calcium were given. Nevertheless, the risk of spinal fractures did not appear to be reduced.

In a trial involving 944 healthy Icelandic adults, Steingrimsdottir et al.[8] found that with 25-OHD levels below 10 ng/mL (i.e., significant vitamin D deficiency), maintaining calcium intake above 800 mg/day appeared to normalize calcium metabolism, as determined by the PTH level, but in individuals with higher 25-OHD levels, no benefit was observed from calcium intake above 800 mg/day.

In 2005 and 2006, three major papers were published discussing the relationship between calcium, vitamin D, and osteoporotic fracture risk. Findings from the RECORD study, published in *The Lancet* (2005), suggested a lack of benefit from concomitant calcium and vitamin D in the prevention of fractures in menopausal women.[40] Subsequently, Jackson et al.[302] published a paper using data from the Women's Health Initiative that questioned the assumption that calcium and vitamin D can prevent osteoporosis-related hip fractures. They randomly assigned 36,000 postmenopausal women to receive elemental calcium, as calcium carbonate (500 mg twice daily), plus vitamin D (200 IU twice daily) or a placebo for an average of 7 years. Notably, the average calcium consumption in both groups was approximately 1150 mg/day, close to the appropriate recommended intake level. After 7 years, subjects in the treatment group exhibited 12% fewer hip fractures than did those in the placebo group, a finding that was not statistically significant. However, a deeper analysis of the data reveals that more significant differences appear when considering compliance and initial calcium intake levels. For example, after excluding women who were not adhering to the program, the

reduction in fractures was greater, with 29% fewer fractures in the treatment group than in the placebo group, a statistically significant difference. Likewise, hip fracture risk decreased by about 22% in treated subjects whose initial calcium intake was low or moderate, but increased by 12% in treated women with high initial calcium intake (≥ 1200 mg/day).[302] Overall, in both trials compliance was only on the order of 40% and 50%.

In contrast, Boonen et al.[303] conducted a multifaceted meta-analysis of major randomized placebo-controlled trials that analyzed the effects of vitamin D alone or in combination with calcium. In one analysis they found that randomized clinical trials comparing vitamin D alone to placebo showed no effect. Likewise, a subsidiary analysis showed that low doses of vitamin D, less than 800 units/day, exerted no effect. However, they demonstrated a statistically significant 21% reduction in risk of fracture, compared to placebo, among subjects receiving 800 IU vitamin D and more than 1000 mg calcium daily. The authors concluded that vitamin D exerts its beneficial effect on bone predominantly by increasing absorption of calcium.

In some individuals and with certain medical conditions, supplementation with vitamin D, particularly at levels significantly in excess of those needed to overcome established deficiency, can induce an excessive increase in the absorption of calcium and increase the risk of hypercalcemia and kidney stone formation.[302] The risk of such adverse effects occurring may be influenced by the form of calcium used, as well as other, individual patient variables. Emerging evidence and the opinions of many vitamin D researchers now suggest, however, that the daily value (DV) of 400 IU for vitamin D, which was based on the amount necessary to prevent rickets in infants (initially given as 5 mL of cod liver oil 100 years ago) is an order of magnitude below the amount necessary for older adults and those not regularly exposed to sun without sunscreen to achieve and maintain blood levels of vitamin D that are optimum for bone health and cancer prevention.[304-316] "Estimates of the population distribution of serum 25(OH)D values, coupled with available dose-response data, indicate that it would require input of an additional 2600 IU/d (65 mcg/d) of oral vitamin D_3 to ensure that 97.5% of older women have 25(OH)D values at or above desirable levels."[317] Absent lymphoma or granulomatous disease, which can cause vitamin D sensitivity, it appears that long-term ingestion of greater than 10,000 IU/day is necessary to cause vitamin D toxicity and hypercalcemia.

Zinc

Most available evidence from human studies indicates that simultaneous administration of calcium and zinc decreases GI absorption of zinc.[275,318-323] Research based on antacids suggests that calcium can interfere with the absorption of zinc (and possibly other minerals) by neutralizing stomach acid.[277] However, clinically adverse significant effects on bioavailability or status of either mineral are improbable. In particular, when ingested in the presence of meals, zinc levels appear to be unaffected by increases of either dietary or supplemental calcium.

The 323 citations for this monograph, as well as additional reference literature, are located under Calcium on the CD at the back of the book.

Chromium

Nutrient Name: Chromium.
Synonyms: Chromium 3, chromium acetate, chromium aspartate, chromium chloride, chromium histidine, chromium nicotinate, chromium picolinate, chromium polynicotinate, chromium sulfate, trivalent chromium; Cr(III), Cr^{+3}.
Elemental Symbol: Cr.
Related Substances: Brewer's yeast, high-chromium yeast; hexavalent chromium (VI; Cr^{+6}; toxic).

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Beta-1-Adrenoceptor Antagonists ⊕⊕	Patients on beta-blocker therapy may derive improvements in lipid status, particularly elevations in HDL cholesterol, with concomitant chromium administration. Preliminary evidence primarily involved middle-aged men with hypertension, but findings may reasonably be extrapolated to other patient populations.	Coadminister. Standard monitoring usually adequate.
Corticosteroids, oral ≈≈/☼	Increased chromium excretion is associated with corticosteroid therapy and may play a role in steroid-induced diabetes. Coadministration can prevent drug-induced depletion and may reverse steroid-induced diabetes.	Coadminister. Standard monitoring usually adequate.
Insulin, glyburide, metformin Oral hypoglycemic agents ⊕⊕/⊕ X/X	Compromised chromium status is quite common and may contribute to insulin resistance, dysglycemia, and onset of diabetes. Chromium potentiates insulin activity through multiple mechanisms, only some of which are well known, and is most active in those with chromium deficiency. Coadministration of chromium with exogenous insulin or oral hypoglycemic medications may provide therapeutic benefit by enhancing insulin activity and glucose control. However, inappropriate combining could induce hypoglycemic reaction.	Coadminister, especially with probable deficiency. Modify dosing of both agents gradually with titration. Monitor for hypoglycemic symptoms.
Sertraline Selective serotonin reuptake inhibitor (SSRI) antidepressants ⊕⊕	Disparate and indirect evidence indicates that chromium may benefit individuals with depression through effects on glucose control and potentiation of insulin. In particular, chromium picolinate appears to increase peripheral availability of tryptophan for brain serotonin (5-HT) synthesis and alter sensitivity of central 5-HT(2A) receptors. Clinical trials have reported increased efficacy (including efficacy in therapy-refractory patients) of standard antidepressant treatment, specifically sertraline, with coadministration. No evidence of adverse effects has been presented.	Coadministration judicious and considered safe, especially with probable deficiency. Standard monitoring usually adequate.

NUTRIENT DESCRIPTION

Chemistry and Forms

Chromium exists in several forms, with chrome-iron ore the predominant form in the planetary crust. The trivalent and hexavalent states constitute the most common valence states, with trivalent chromium being the stable and biologically active form found in most food sources and hexavalent chromium primarily associated with industrial exposure and toxicity.

Physiology and Function

Chromium is an essential trace mineral well known for its role in carbohydrate, lipid, and protein metabolism in general and insulin activity and glucose homeostasis in particular. Emerging knowledge indicates that chromium also plays an important role in nucleic acid synthesis and gene expression. Nevertheless, chromium, as an ultratrace element, is found in very low concentrations in the human body.

Dietary chromium is poorly absorbed (0.5% to 2.8% of intake), and almost all of an ingested dose is excreted in the feces. Absorption occurs in the small intestine by processes other than simple diffusion, the mechanisms of which are not yet fully understood. Chromium is subsequently transported in the serum or plasma bound to transferrin (named for its role in binding and transporting iron) primarily and albumin secondarily. Chromium is widely distributed throughout the human body, with highest concentrations in the bone, spleen, liver, and kidney into four different compartments that have rapid, medium, slow, and very slow turnover. Chromium that has been absorbed is excreted mainly in the urine. Small amounts are also lost in hair and sweat. Little excretion occurs via the biliary route.

Organic chromium increases insulin sensitivity, promotes glucose uptake, and potentiates the action of insulin by increasing insulin binding to cells, increasing the number of insulin receptors, and activating insulin receptor kinase. Trivalent chromium serves as the active component of a substance called *glucose tolerance factor* (GTF), along with nicotinic acid (a form of vitamin B_3) and amino acids in the form of a small oligopeptide known as *chromodulin*, or low-molecular-weight chromium-binding substance (LMWCr). Once activated by binding to chromium, chromodulin binds to insulin-activated insulin receptors in insulin-dependent cells and participates in auto-amplification of insulin signaling, thereby stimulating its tyrosine kinase activity and potentiating

the activity of insulin. Chromium may also inhibit tyrosine phosphatase, which inactivates the insulin receptor. Such combined effects on insulin receptor kinase activity and tyrosine phosphatase would lead to increased phosphorylation of the insulin receptor and an associated increase in insulin sensitivity. Thus, through GTF, chromium acts as a cofactor to mediate the activity of insulin and facilitate glucose transport across cell membranes.

Chromium appears to possess hypocholesterolemic and antiatherogenic activities. Chromium can decrease levels of total cholesterol, low-density lipoprotein (LDL) cholesterol, and apolipoprotein B and may increase levels of high-density lipoprotein (HDL) cholesterol. The possible antiatherogenic activity of chromium is most likely derived from its glucose-regulatory activity. Chromium, like insulin, also increases uptake of amino acids into muscle, heart, and liver and enhances protein synthesis.

At this time, chromium remains the only essential transition metal whose mechanism of action has not been fully elucidated.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

In 1957, researchers observed impaired glucose tolerance in chromium-deficient rats and discovered that administration of a chromium-containing compound extracted from pork kidney to diabetic rats maintained normal glucose tolerance and enabled more efficient use of insulin. They called this substance "glucose tolerance factor" (GTF). Later, other researchers reported an increased occurrence of glucose intolerance, weight loss, and peripheral neuropathy in patients receiving long-term total parenteral nutrition (TPN) without chromium. Intravenous administration of chromium chloride reversed these symptoms. Over the subsequent decades, chromium research has grown, with an emerging consensus confirming its therapeutic value in supporting insulin activity and glucose homeostasis. Wide-ranging and unresolved controversy surrounds its purported efficacy in weight loss, athletic training, dyslipidemia, depression, hyperactivity, and related conditions. Rigorous, blinded, and well-controlled studies of sufficient size and power are needed to assess fully the efficacy and mechanism of action of chromium administration and to establish clinical guidelines for its role within an integrative strategy for type 2 diabetes and impaired glucose tolerance.

Historical/Ethnomedicine Precedent

Based on familiarity with folk medicine traditions and empirical practice, naturopathic physicians and other practitioners of nutritional therapeutics have advocated the administration of brewer's yeast and foods rich in chromium for the prevention and treatment of hypoglycemia and diabetes for more than a century.

Possible Uses

Acne, atherosclerosis, athletic performance, atypical depression, depression, diabetes mellitus type 1, diabetes mellitus type 2, dysthymic disorder, gestational diabetes, glaucoma, hypercholesterolemia, hypertriglyceridemia, hypoglycemia, insulin resistance syndrome (metabolic syndrome/syndrome X), low HDL cholesterol, migraine, obesity, polycystic ovarian syndrome (PCOS), premenstrual syndrome (PMS), psoriasis, Turner's syndrome, weight loss.

Deficiency Symptoms

Suboptimal chromium intake is widespread, with as much as 90% of American diets low in chromium. Nevertheless, gross chromium deficiency is rare. Clinically, chromium deficiency was first characterized in three patients receiving long-term TPN lacking chromium. Compromised chromium status is most common in the elderly, individuals with diets high in simple carbohydrates and refined foods, pregnant women, and individuals experiencing extended periods of physiological stress, including those with chronic infections or those who regularly engage in strenuous exercise. Well-controlled studies have demonstrated chromium depletion in subjects with chromium intake level of 5 µg/1000 kcal. The primary sign of marginal chromium deficiency is impaired glucose tolerance, characterized by elevated levels of blood glucose and elevated circulating insulin concentration. Long-term deficiency results in elevated circulating cholesterol and triglyceride concentrations. Other observed effects include glycosuria, fasting hyperglycemia, hypoglycemia, decreased insulin binding, decreased insulin receptor number, impaired growth, central and peripheral neuropathy, and impaired humoral immune response. In many respects, chromium deficiency symptoms parallel those of diabetes. Low levels of chromium are also associated with increased risk of cardiovascular disease.

Dietary Sources

The amount of chromium in foods is variable because the actual chromium content in many foods can vary significantly in different batches of the same food. Brewer's yeast (particularly yeast grown in chromium-rich soil), lean meats (especially processed meats), oysters, liver and other organ meats, beer, and potatoes are relatively high in chromium. Seafood, whole grains, cheeses, chicken, bran, mushroom, oatmeal, prunes, nuts, broccoli, green beans, and asparagus are intermediate in chromium content. Most vegetables, fruit, refined grains, and processed foods (except for processed meats) contain low amounts of chromium. Notably, foods high in simple sugars, such as sucrose and fructose, not only are low in chromium content, but also are known to promote chromium loss.[1]

Note: Nutritional yeast and torula yeast do not contain significant amounts of chromium.

Nutrient Preparations Available

Several forms of trivalent chromium are available as stand-alone supplements or within combination nutrient formulations. Organic forms are preferable, including chromium aspartate, chromium histidine, chromium nicotinate, chromium picolinate, chromium polynicotinate, high-chromium yeast, and chromium-GTF. Chromium picolinate was considered the superior form for many years until chromium histidine was introduced by researchers from the U.S. Agricultural Research Service. Anderson et al.[2] found that men and women absorbed an average 3.1 µg of chromium from the chromium-histidine complex, compared with 1.8 µg from chromium picolinate, 0.4 µg from chromium chloride, and 0.2 µg from chromium polynicotinate. Typical maintenance doses of supplemental chromium range from 50 to 200 µg daily, expressed as elemental chromium. Chromium is best administered between meals, preferably in divided doses.

Dosage Forms Available

Capsule, tablet.

Source Materials for Nutrient Preparations

Trivalent chromium: Salt formed with picolinic acid, chloride, sulfate, nicotinic acid (niacin), or amino acid chelates, such as with histidine. Some forms of supplemental chromium are combined with GTF extracted from brewer's yeast.

Dosage Range

In recognition of the inadequacy of available data on chromium requirements the Food and Nutrition Board (FNB) of the U.S. Institute of Medicine proposed an adequate intake level (AI) based on the chromium content in normal diets rather than establish a recommended dietary allowance (RDA).

Adult

Dietary: Estimated average chromium intakes in the U.S. range from 23 to 29 µg per day for adult women and 39 to 54 µg per day for adult men.[3] The estimated safe and adequate daily dietary intake (ESADDI) for adults is 50 to 200 µg.
Supplemental/Maintenance: 50 to 200 µg/day.

The AI for chromium in adult males is 30 to 35 µg per day and for females 20 to 25 µg per day (except while pregnant or lactating).
Pharmacological/Therapeutic: 200 to 3000 µg/day.

An individual's requirement for chromium parallels their degree of glucose intolerance.
Toxic: Some initial research indicated that doses as low as 300 µg per day were potentially toxic over extended periods. In the United States (U.S.), no tolerable upper level of intake (UL) has been set for chromium by the FNB. However, in the United Kingdom (U.K.) in 2004 the Food Standards Agency (FSA) established a maximum upper level of 10 mg (10,000 µg) elemental chromium from chromium picolinate per day.

Pediatric (< 18 Years)

Dietary: Breast-fed infants consume less than 1 µg/day.

Infants, 7 to 12 months: 5.5 µg/day (AI, adequate intake)
Children, 1 to 3 years: 11 µg/day (AI)
Children, 4 to 8 years: 15 µg/day (AI)

Supplemental/Maintenance: None established.
Pharmacologic/Therapeutic: 1 to 50 µg/day.
Toxic: None established.

Laboratory Values

No biomarker has established itself as the standard for assessing chromium status and distinguishing adequate or deficient chromium levels.

Serum chromium: Less than 2.0 nmol/L may indicate chromium deficiency, but this is a relatively insensitive indicator of tissue stores.
Whole-blood chromium: Normal range: 14 to 185 nmol/L.
Urinary chromium: Normal range: approximately 3 to 4 nmol/L; greater than 38 nmol/L indicates toxicity.

These tests have generally been considered to be of limited value in assessing status because of the extremely low concentrations of chromium present in biological tissues and fluids, and because these tests have only limited sensitivity in measuring response to chromium intake. Thus, they have primarily been used to measure overexposure to environmental chromium. Neutron activation analysis, mass spectrometry, and graphite furnace atomic absorption spectrometry represent the only analytical techniques with the required sensitivity to adequately provide clinically relevant measurements. However, these analytical methods are not widely available, are susceptible to interference from the sample matrix, and are too expensive to be clinically applicable. Additional investigation of urinary chromium in response to very low levels of intake has been suggested.

In a randomized, double-blind, crossover design involving 78 non-insulin-dependent diabetes mellitus patients, Bahijri and Mufti[4] (2002) found that both brewer's yeast and chromium chloride caused a significant increase in the mean values of urinary chromium (Cr) and a significant decrease in the means of glucose and fructosamine, concluding that "urinary Cr response to glucose load could be used as an indicator of Cr status."

SAFETY PROFILE

Overview

The limited safety data available suggest that chromium supplements are generally well tolerated at usual dosage levels. Both solubility and oxidation state affect the potential for toxicity. Furthermore, the type of complex may impact toxicity. There have been reports of toxic reactions to chromium picolinate at doses significantly higher than those typically used. No cause-effect relationship has been confirmed in human research. After several years of controversy regarding the potential toxicity of chromium, especially chromium picolinate, a consensus emerged in 2004 supporting the safety of chromium as a nutritional supplement.

Long-term daily intake of trivalent chromium (Cr^{+3}) and chromium in brewer's yeast in the range of 50 to 300 µg is generally considered safe. Supplementation with chromium picolinate at daily dosage levels of up to 1000 µg for as long as 64 months in adults has produced no adverse effects.[5-7] Even so, doses greater than 400 µg daily should generally not be taken for extended periods outside the context of care by a health care professional trained in nutritional therapies.

In contrast, chronic exposure to airborne or waterborne hexavalent chromium (Cr^{+6}), such as chromium dust in metalworking, printing, paint, textile, and other industrial settings, is associated with dermatitis and increased risk of lung and other cancers.

Nutrient Adverse Effects

General Adverse Effects

Self-administered chromium picolinate, at relatively high dosage levels, has been associated with adverse effects in a handful of case reports. Two case reports of renal failure, involving women consuming 600 and 1200 to 2400 µg chromium picolinate daily for 6 weeks and 5 months, respectively, have not been qualified to establish a causal link.[8,9] Toxic reactions to chromium picolinate have also been suspected in individual cases of interstitial nephritis, liver and kidney damage, thrombocytopenia, acute generalized exanthematous pustulosis, and rhabdomyolysis.[9-12] However, the dosage levels described in these unqualified reports are generally not recommended, especially outside the context of professional supervision.

Isolated in vitro evidence, mixed and still inconclusive, has suggested that chromium picolinate in high concentrations may be clastogenic. However, if proven, the picolinate component, rather than the chromium, might be the mutagenic factor because no reports have involved chromium chloride or chromium nicotinate. In vivo animal studies arrived at mixed conclusions. The significance of these results on humans taking the supplement for prolonged periods is unknown. In the U.K. the Committee on Mutagenicity commissioned by the FSA conducted a thorough genotoxicity review and, based on their recommendation, concluded that available evidence supported the safety of chromium at doses up to 10 mg per day. Nevertheless, judicious practice suggests that long-term intake of chromium picolinate, particularly at doses higher than 400 µg daily, are best undertaken under supervision of a health care professional trained and experienced in nutritional therapeutics. Continued study and postmarket surveillance is warranted.

Adverse Effects Among Specific Populations

The risk of chromium toxicity could theoretically be greater in individuals with preexisting liver or kidney disease.[3]

Pregnancy and Nursing

The maximum safe dosage levels of chromium for women who are pregnant or nursing have not been established. However, in a study involving 10 women administered 400 µg chromium picolinate daily, Kato et al.[13] found no evidence of increased oxidative damage to DNA, as measured by antibody titers to an oxidized DNA base of 5-hydroxymethyl uracil.

Chromium appears to be safe when used to improve glycemic control in gestational diabetes.[14] Furthermore, chromium appears safe in lactation when used orally; supplements do not appear to increase normal chromium concentration in human breast milk.[15]

Infants and Children

The maximum safe dosage levels of chromium for infants and children have not been established.

Contraindications

Chromium is contraindicated in those hypersensitive to any component of a chromium-containing formulation. Sensitivity to yeast warrants avoidance of yeast-derived or yeast-containing forms of chromium.

Precautions and Warnings

Pregnant women and nursing mothers should avoid doses of chromium greater than 50 µg per day.

Caution and professional supervision may be appropriate when introducing chromium to individuals with a history of hypoglycemia. Conversely, those with a history of hyperglycemia or type 2 diabetes mellitus who are taking prescription medications for blood sugar control should only initiate, use, or significantly change dosage levels of chromium supplements within the context of professional supervision and close monitoring.

Concern has been expressed that chromium picolinate might be contraindicated for individuals with depression, bipolar disease, or schizophrenia because picolinate can alter levels of neurotransmitters and chromium picolinate may decrease the sensitivity of 5-HT(2A) receptors by increasing the peripheral availability of tryptophan for brain serotonin (5-HT) synthesis.[16,17]

INTERACTIONS REVIEW

Strategic Considerations

For decades, chromium has played a central role in the prevention and treatment of hypoglycemia, insulin resistance, glucose intolerance, and diabetes mellitus within the clinical practice of nutritional therapeutics and natural medicine. Chromium is rarely, if ever, relied on as a monotherapy, or even a dominant intervention, within such a context. Exercise and lifestyle modification, balanced diet emphasizing low glycemic index/load foods, moderately high protein intake, and healthy fats and oils, along with individualized programs of nutrients and herbs, constitute the components of a more typical strategy.

Although often used in the treatment of dysglycemia in general, and hypoglycemic tendencies and insulin resistance in particular, chromium can also help prevent diabetes in susceptible individuals and play an adjunctive role in the treatment of diabetes. The dietary chromium intake of most individuals in the U.S. does not meet the level of 50 to 200 µg per day recommended by the U.S. National Academy of Science. Many clinicians and researchers have noted the parallels between suboptimal chromium levels, high intake of simple carbohydrates and sugars, and the escalating rates of insulin resistance and obesity, diabetes, and heart disease. An emerging pattern of evidence, but as yet not consistent, comprehensive, or conclusive, indicates that chromium may also improve lipid status by increasing HDL cholesterol and lowering total cholesterol. Furthermore, individuals with diabetes often have additional chromium depletion as a result of the disease process itself. Collectively, these findings suggest strongly that chromium may play a significant role in the prevention of heart disease through a variety of interconnected influences. Notably, chromium supplementation may also be of benefit in the treatment of individuals with Turner's syndrome through its effect on glucose tolerance. Preliminary research suggesting that chromium can reduce body fat, induce weight loss, and enhance lean muscle gain is intriguing and consistent with known activity, but has yet to be supported by a consistent and substantive body of evidence based on clinical trials of adequate size, strength, and design. At this point, the consistent theme in chromium research is that its therapeutic effect is greatest in individuals with diets low in chromium.

Chromium administration at typical dosage levels is generally unlikely to result in adverse effects or interactions with conventional medications. The available evidence regarding chromium interactions indicates that the use of supplemental chromium within the context of an integrative care model is likely to be safe and may provide added therapeutic benefits with reasonable administration and standard monitoring. In particular, concomitant use of chromium by diabetic patients introduces a high probability of enhanced insulin activity in response to the influence of the nutrient, especially in the context of suboptimal chromium intake and a diet high in refined carbohydrate foods, which contributes to both inadequate intake and increased urinary excretion. Thus, extra monitoring through stabilization may be required with chromium coadministration in patients being treated with conventional antidiabetic medications, such as insulin or oral hypoglycemic agents, because dosage requirements may be reduced as sensitivity of the insulin receptors to insulin increase.

Further research in all these areas is warranted. The findings likely to emerge over the coming decade will undoubtedly

assist in clarifying knowledge, understanding, and effective clinical application of chromium in supporting healthy glucose regulation, preventing dysfunction of insulin and lipid metabolism, and treating resultant pathology.

NUTRIENT-DRUG INTERACTIONS

Beta-1-Adrenoceptor Antagonists (Beta-1-Adrenergic Blocking Agents)

Oral forms (Systemic): Acebutolol (Sectral), atenolol (Tenormin); combination drugs: atenolol and chlorthalidone (Co-Tendione, Tenoretic); atenolol and nifedipine (Beta-Adalat, Tenif); betaxolol (Kerlone), bisoprolol (Zebeta), carteolol (Cartrol), esmolol (Brevibloc), labetalol (Normodyne, Trandate), metoprolol (Lopressor, Toprol XL); combination drug: metoprolol and hydrochlorothiazide (Lopressor HCT); nadolol (Corgard), nebivolol (Nebilet), oxprenolol (Trasicor), penbutolol (Levatol), pindolol (Visken), propranolol (Betachron, Inderal LA, Innopran XL, Inderal); combination drug: propranolol and bendrofluazide (Inderex); sotalol (Betapace, Betapace AF, Sorine), timolol (Blocadren).

Interaction Type and Significance

◉ **Emerging**

Effect and Mechanism of Action

Chromium supplementation may improve levels of HDL cholesterol through a mechanism that has not yet been fully elucidated.

Research

In a randomized, double-blind, placebo-controlled trial involving 63 men receiving beta-blocker therapy, primarily for hypertension, Roeback et al.[18] observed modest increases in HDL cholesterol levels after administration of 200 µg three times daily of "biologically active chromium" in the form of "glucose tolerance factor (GTF)–chromium" for 8 weeks.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing beta blockers to individuals with hypertension can discuss with patients the potential benefits of adding chromium (e.g., 200 µg three times daily) to a comprehensive regimen for improving HDL cholesterol status as well as stabilizing glucose levels and generally reducing cardiovascular risk. Although not conclusive, these preliminary findings are promising in suggesting a potential role for chromium within an integrative strategy aimed at addressing the intertwining issues of dysglycemia, insulin resistance, hypertension, and cardiovascular risk. Furthermore, caution is appropriate in not summarily extrapolating from these findings based on men to presumed applicability to women. Further research through well-designed, long-term clinical trials is warranted to investigate the implications of this potential synergy and guide formulation of therapeutic options.

Corticosteroids, Oral

Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol) prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Corticosteroid therapy increases chromium excretion; this effect may play a role in the development of corticosteroid-induced glucose intolerance and diabetes. Chromium coadministration may reverse steroid-induced diabetes.

Research

Ravina et al.[19] measured the effects of corticosteroid treatment on chromium losses in 13 patients 2 days before steroid administration and 3 days after treatment. They observed that urinary chromium losses after corticosteroid treatment increased significantly in the first 3 days following treatment. These researchers also reported that administration of 600 µg/day of chromium (as chromium picolinate) to three patients with steroid-induced diabetes "resulted in decreases in fasting blood glucose values from greater than 13.9 mmol/L (250 mg/dL) to less than 8.3 mmol/L (150 mg/dL)." Notably, hypoglycemic drugs were also "reduced 50% in all patients when given supplemental chromium."[19]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing oral corticosteroids, especially for extended periods and at high dosage levels, are advised to coadminister chromium, 200 µg three times daily, to counter drug-induced chromium excretion, support glucose control and insulin sensitivity, and prevent corticosteroid-induced diabetes. Patients being treated with hypoglycemic agents will require supervision and monitoring because gradual decreases in medication levels will often be appropriate in response to the effects of chromium administration. Further research through well-designed, long-term clinical trials is warranted to investigate the implications of this potential synergy and guide formulation of therapeutic options.

Insulin, Glyburide, Metformin, and Related Oral Hypoglycemic Agents

Insulin: Animal-source insulin (Iletin); human analog insulin (Humanlog); human insulin (Humulin, Novolin, NovoRapid, Oralin).

Biguanides: Buformin (Andromaco Gliporal, Buformina), metformin (Dianben, Glucophage, Glucophage XR), phenformin (Debeone, Fenformin).

Sulfonylureas: Acetohexamide (Dymelor), chlorpropamide (Diabinese), glimepiride (Amaryl), glyburide (Diabeta, Glibenclamide, Glynase Prestab, Glynase, Micronase, Pres Tab), glipizide (Glucotrol; Glucotrol XL), tolazamide (Tolinase), tobutamide (Orinase; Tol-Tab).

Combination drugs: Glipizide and metformin (Metaglip); glyburide and metformin (Glucovance).

Extrapolated, based on similar properties: **Alpha-glucosidase inhibitors:** Acarbose (Glucobay, Precose).

Meglitinide Analog Oral Hypoglycemics: Nateglinide (Starlix), repaglinide (Prandin).
Thiazolidinediones (glitazones): Pioglitazone (Actos), rosiglitazone (Avandia).

Effect and Mechanism of Action

In vitro, in vivo, and human studies indicate that chromium participates in glucose and lipid metabolism, influences circulating insulin levels, and potentiates the peripheral activity of insulin.[20-23] Chromium has been observed to improve insulin binding, insulin receptor number, insulin internalization, beta-cell sensitivity, and insulin receptor–related enzymes, with overall increases in insulin sensitivity. The proposed mechanism of action for chromium's effect is, at least in part, caused by enhanced intracellular tyrosine kinase activity that results from an interaction between chromium, chromodulin, and activated cell-surface insulin receptors.[24] Other research suggests that the potential in vivo mechanism of chromium (picolinate) on insulin action in human skeletal muscle may occur by increasing the activation of Akt phosphorylation.[25] This intracellular insulin-dependent protein facilitates the uptake of glucose into cells. Furthermore, by downregulating pancreatic islet beta-cell activity, chromium may increase glucagon secretion.[26] Nevertheless, at this time, knowledge of the biochemical basis underlying these reported and hypothesized effects remains conflicting and evolving.

Exogenous insulin therapy is designed to augment or replace endogenous insulin in individuals lacking sufficient synthesis capacity in the islets of Langerhans of the pancreas. Oral sulfonylureas (e.g., glyburide) act by stimulating the production and release of insulin (not sensitivity, or at least not primarily), and as such, these agents can only be used in patients with an intact pancreas with functioning islet cells. There are probably other activities of the oral drugs, but at one level, both insulin and oral hypoglycemic agents simply increase the amount of available insulin, one exogenously and the other endogenously. In most type 1 diabetic patients the islet cells have undergone autoimmune destruction, so the sulfonylurea-based agents are not useful. To the degree that type 1 diabetic individuals have chromium insufficiency and decreased insulin receptor sensitivity, increased dietary chromium may have benefit, but virtually all will require some exogenous insulin therapy.

Research

Numerous clinical trials, some well-designed, others less so, have demonstrated the ability of chromium to potentiate insulin and improve glucose control, especially in diabetic patients and individuals with less-than-optimal chromium intake. The nutritional biochemistry, physiological function, and therapeutic applications of chromium are gradually becoming elucidated. Consequently, studies on the effectiveness of chromium administration in patients with glucose intolerance and type 2 diabetes have produced findings that are inconsistent and evolving. These conflicting results are caused by many factors, including characteristics of subject population, concomitant medications and dietary influences, dose and form of chromium used, and duration of therapy.

Numerous studies have shown an association between chromium deficiency and impaired glucose regulation, onset of type 2 diabetes in susceptible individuals, and increased risk for lipid disorders and cardiovascular diseases.[27-34] The pathophysiology of diabetes itself may exacerbate chromium deficiency. For example, urinary loss of chromium is elevated in individuals with type 2 diabetes resulting, at least in part, from glycosuria. Thus, plasma chromium levels are about 40% lower in diabetic subjects compared with healthy individuals. In a symposium at the 59th annual scientific sessions of the American Diabetes Association (1999), Cefalu described an improvement in insulin sensitivity in obese people with prediabetic symptoms who received chromium picolinate. Conversely, excess chromium intake may result in tissue accumulation and subsequently could, at least theoretically, inhibit rather than enhance insulin activity. Findings from a rat study suggest that a chromium-induced increased in hepatic insulin clearance may offset the improvement in insulin sensitivity in some diabetic individuals, such that glycemic control might not improve appreciably.[35] Adequate and balanced chromium nutriture is clearly essential for normal insulin activity and glucose control. However, given the lack of human studies suggesting such effects of excess supplemental chromium intake and the low oral absorption of chromium compounds, it may be quite difficult to induce chromium excess with oral supplementation, especially in diabetic patients, with their tendency toward increased chromium excretion. These considerations are further supported by the safe upper limit of 10 mg daily established by the U.K. regulatory authorities.

Administration of chromium picolinate may help prevent or delay the need for antidiabetic medication and can often be used synergistically with such medications once they have been prescribed. The most relevant data indicate that chromium picolinate improves clinical results when used in combination with standard treatments, including insulin, sulfonylureas, or metformin alone and in combinations. Improvements have been observed in glucose tolerance tests in adult diabetic patients[36,37] and in glucose-intolerant men and women.[38-40] Uusitupa et al.[41] reported that administration of chromium produced a beneficial effect on insulin response at 1 hour but no improvement in glucose tolerance tests in non-insulin-requiring diabetics. However, researchers in three trials found no significant benefit of chromium with glucose tolerance, insulin levels, or blood lipid concentrations.[42-44]

Notably, in two of these studies, one used chromium chloride, which is poorly absorbed, and the other a low dose (200 µg/day) of chromium picolinate.

In a clinical trial involving 243 individuals with type 1 (105) and type 2 (138) diabetes, Ravina and Slezack[45] found that chromium supplementation (200 µg/day) decreased insulin, sulfonylurea drug, and metformin requirements in a significant number (115) of subjects. "The success rate was greater in those with NIDDM (57.2%) than in those with IDDM (33.6%). More women, of either type, reacted than men (62.5 vs. 50% in NIDDM and 37.6 vs. 28.6% in IDDM)." This trial exhibited major limitations; although frequently described as a controlled clinical trial, this study was largely open label in design with only 10 subjects enrolled in a double-blind protocol. In a subsequent placebo-controlled trial involving 48 patients with type 1 diabetes and 114 patients with type 2 diabetes, Ravina et al.[46] compared diets

supplemented with chromium picolinate (200 µg/day) with placebo. They reported a reduced need for insulin or oral hypoglycemic medications in approximately 70% of patients coadministered chromium. Again, it is notable that trials using 1000 µg (1 mg) of chromium picolinate per day in diabetic patients show a strong positive trend.

Anderson et al.[6] conducted a promising but controversial randomized, placebo-controlled trial involving 180 Chinese men and women with type 2 diabetes, comparing the effects of 1000 µg chromium, 200 µg chromium, and placebo. The therapeutic response appeared to be dose related. The group receiving 1000 µg demonstrated significant improvements in lipids and hemoglobin A_{1c} (HbA_{1c}) values after 2 months; both groups receiving chromium showed such changes after 4 months. Fasting glucose was also lower in the higher dose (1000 µg) chromium group at 2 and 4 months, although no such change observed in the moderate (200 µg) chromium group. Serum insulin levels decreased significantly in both groups at 2 and 4 months.[6] The high dose used might be considered a strength of this trial because it is closer to the dosage levels found to be effective in clinical practice using monotherapy chromium in pharmacological doses. However, the characteristics of the Chinese patient population in this study may limit the applicability of its findings to patient populations in Europe and North America. Furthermore, the large number of subjects in this study has excluded it from some meta-analyses because it would overwhelm data from other, smaller trials.[47]

In a 4-month trial, Bahadori[48] and a team of Austrian researchers studied the effects of chromium picolinate (500 µg twice daily) in 16 obese patients with type 2 diabetes who were pretreated with, and continued to receive stable doses of, a sulfonylurea and metformin. These researchers reported that chromium picolinate appeared to enhance the effects of metformin and oral sulfonylureas. Chromium coadministration was associated with significant reductions in fasting insulin levels, without a detrimental effect on glucose control. Insulin resistance assessed by the insulin suppression test was not affected. They concluded that the positive effects seen in this clinical study could be associated with an effect of chromium picolinate on insulin clearance.

In a double-blind crossover trial involving 78 type 2 diabetic patients, Bahajri et al.[33] investigated the effects of brewer's yeast (23.3 µg Cr daily) and chromium chloride (200 µg Cr daily) sequentially with placebo in between, through four stages, each lasting 8 weeks. They found that both forms of chromium caused a significant decrease in the mean values of glucose (fasting and 2-hour post–glucose load), fructosamine, and triglycerides. The means of HDL cholesterol and serum and urinary chromium were all increased. Furthermore, the mean drug dosage decreased slightly (and significantly in an individual taking glibenclamide) after both supplements; some patients no longer required insulin. These researchers also noted that a higher percentage of subjects responded positively to brewer's yeast chromium.

In 2003, at the 18th International Diabetes Federation Congress, Cefalu et al.[25] presented the findings from a subsequently published double-blind, placebo-controlled trial involving two cohorts of patients with type 2 diabetes who were treated with either sulfonylureas or a diet program and randomized to receive either chromium picolinate (1000 µg/day) or placebo. Hyperinsulinemic, euglycemic clamp studies were used to measure insulin sensitivity and assess the efficacy of glucose uptake on all subjects before randomization and at the end of the study. Of the 16 subjects, those administered chromium picolinate demonstrated a mean increase in insulin sensitivity of 8.9%, whereas those receiving placebo had a mean decrease of 3.6%. In addition, insulin-stimulated Akt activation was significantly increased at the end of the study compared with subjects on placebo. The authors stated that the enhanced activity of Akt phosphorylation associated with chromium administration in individuals with type 2 diabetes represents a possible mechanism to explain chromium picolinate's beneficial effect on insulin sensitivity.[25]

Rabinovitz et al.[49] conducted a controlled clinical trial involving 39 diabetic subjects, average age 73 years (18 males and 21 females), undergoing rehabilitation after stroke or hip fracture, who received 200 µg chromium twice a day for a 3-week period. Both the treated group and a control group of 39 diabetic patients continued their standard treatment for diabetes and received a diet of approximately 1500 kcal/day. At the end of the study, these researchers measured significant differences in the fasting blood level of glucose compared to the baseline (190 vs. 150 mg/dL, $p < 0.001$), improvements in HbA_{1c} from 8.2% to 7.6% ($p < 0.01$), and reductions in total cholesterol from 235 to 213 mg/dL ($p < 0.02$). They also observed a trend toward lowered triglyceride levels. They concluded that, "in this population of elderly, diabetic patients undergoing rehabilitation, dietary supplementation with chromium is beneficial in moderating glucose intolerance."[49]

An overview of the most relevant literature shows that nine single-blind and double-blind trials over 10 years, involving 1349 total subjects, produced findings that are consistent. These studies concentrated on the effects of chromium picolinate on markers of blood glucose or on insulin regulation in subjects with type 2 diabetes or in individuals with induced diabetes. Overall, they found that chromium picolinate exerts a beneficial effect on fasting insulin values and on HbA_{1c}.[6,19,46,48,50-55] Cefalu et al.[52] and Morris et al.[56] have suggested that chromium picolinate increases insulin sensitivity and glucose utilization and maintains normal blood glucose concentrations. Many human studies have also reported that administration of chromium is associated with improvements in lipids, particularly triglycerides, LDL and HDL cholesterol,[57,58] and lipoprotein(a), as well as other benefits for coronary disease risk profiles that are important in both diabetic and nondiabetic populations. Nevertheless, in reviewing much of the same literature in a 2002 meta-analysis, Althuis et al.[47] concluded that "data from randomized clinical trials are sparse and inconclusive." Ultimately, everyone in the field agrees that further research emphasizing placebo-controlled, randomized clinical trials in well-characterized, at-risk populations is necessary to determine the effects of chromium, given in the more absorbable forms and in adequate amounts, on concentrations of glucose, insulin, and HbA_{1c}.

The controversy surrounding the efficacy of chromium in diverse populations continues; research has yet to deliver a consistent pattern of findings that might provide an evidence-based foundation for consensus. For example, two papers published in 2006 presented seemingly conflicting results with divergent implications. Following on the research previously mentioned, Martin, Cefalu, et al.[58a] conducted a trial involving 37 subjects with type 2 diabetes in which they first placed subjects, after baseline, on a sulfonylurea (glipizide, 5 mg/day) with placebo for 3 months. They then randomized subjects, in a double-blind fashion, to receive either the glipizide plus continued placebo or the glipizide plus 1000 µg chromium picolinate (CrPic) for 6 months. At the end of the trial period, they found that subjects administered glipizide and placebo, as opposed to those randomized to glipizide and

chromium, exhibited a "significant increase" in body weight (2.2 kg), percent body fat (1.17%), and total abdominal fat (32.5 cm^2) from baseline. Conversely, those subjects receiving glipizide and chromium exhibited "significant improvements in insulin sensitivity corrected for fat-free mass" (28.8), HbA_{1c} (glycosylated hemoglobin) (−1.16%), and free fatty acids (−0.2 mmol/L) "as opposed to sulfonylurea/placebo." The authors concluded that "this study demonstrates that CrPic supplementation in subjects with type 2 diabetes who are taking sulfonylurea agents significantly improves insulin sensitivity and glucose control," and that coadministration of chromium "significantly attenuated body weight gain and visceral fat accumulation compared with the placebo group." In contrast, in a 6-month, double-blind trial involving 53 subjects (46 of whom completed the study), Kleefstra et al.[59] found that, contrary to expectations, "high-dose chromium picolinate" (500 or 1000 µg) does not improve glycemic control or other parameters in "obese patients with poorly controlled, insulin-treated type 2 diabetes." The study participants had an HbA_{1c} greater than 8% and insulin requirements of greater than 50 units per day. The investigators reported that among the three groups, receiving placebo or 500 or 1000 g chromium picolinate daily, the decrease in HbA_{1c}, the primary efficacy measure, was similar (−0.3%, −0.5%, and −0.3% for placebo, 500 µg, and 1000 µg, respectively). Secondary endpoints included changes in lipid profiles, body mass index (BMI), blood pressure, and insulin requirements. Likewise, no differences were observed in BMI, blood pressure, and insulin requirements; notably, however, a weak association was found between an increasing serum chromium concentration and improvement in the lipid profile. In light of the contrast between these results and earlier findings, the authors added: "Whether it is possible to select subgroups of patients with suitable certain phenotypes that may or may not benefit from chromium therapy also needs further attention."[59]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The ongoing epidemic of dysglycemia, insulin resistance, and diabetes, severe problems contributing to lipid disorders and cardiovascular morbidity, forcefully establishes the need to develop an integrative understanding of the therapeutic role of chromium. General agreement exists that chromium intake is inadequate for much of the population, and that compromised chromium nutriture status is common, even (or even more so) in developed countries with processed food–based diets. The body of literature suggests that individuals with diabetes may benefit from chromium administration in many ways, including more stable insulin levels and enhanced glucose control. Although inclusion of chromium in a comprehensive therapeutic strategy may contribute to these and many other potential benefits, the appropriate dosage levels and character of effects may vary among individuals and even change over time for a given patient. Furthermore, because the current data imply that some individuals respond better to chromium picolinate than do others (nonresponders), further research is needed to establish accurate and sensitive laboratory methods to identify the most suitable candidates for treatment with chromium picolinate or other well-absorbed forms, such as GTF or the histidine chelate. To date, the picolinate has been the best studied of the apparently efficacious forms of chromium.

Chromium's ability to enhance endogenous regulation of blood glucose levels, together with its potentiation of insulin's activity, make it a valuable option in stabilizing diabetic physiology, potentially preventing diabetic complications, and eventually reducing dependence on medication. Health care professionals treating individuals with diabetes using conventional medications, natural therapies (e.g., acupuncture, herbs, other nutrients), and lifestyle changes (e.g., diet, exercise) will need to monitor such patients closely if chromium is introduced into the regimen. Thus, patients should be cautioned regarding the potential risks of inadvertent or unsupervised chromium administration in conjunction with conventional treatments, especially pharmaceutical treatments capable of inducing hypoglycemia. In particular, the prescribed dose of insulin or oral hypoglycemic medication may need to be reduced gradually to avoid a hypoglycemic reaction as the patient responds to the actions of chromium. Health care professionals trained and experienced in nutritional therapy typically prescribe chromium at a dosage of 200 µg, once or twice daily; higher dosage may be appropriate based on body surface area or failure to respond to lower doses. Chromium picolinate and chromium histidine are preferred forms.

Sertraline and Related Selective Serotonin Reuptake Inhibitor (SSRI) Antidepressants

Evidence: Sertraline (Zoloft).
Extrapolated, based on similar properties: Citalopram (Celexa), escitalopram (S-citalopram; Lexapro), fluoxetine (Prozac, Sarafem), fluvoxamine (Faurin, Luvox), paroxetine (Aropax, Deroxat, Paxil, Seroxat).

Interaction Type and Significance:
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
4. Plausible to **2. Probable**

Evidence Base:
○ **Preliminary** to ◉ **Emerging**

Effect and Mechanism of Action

Dysglycemia can play an important role in the susceptibility of many individuals to depressive disorders. Chromium may have antidepressant activities in some individuals, at least in part by potentiating the action of insulin. Insulin, in turn, inhibits the reuptake of norepinephrine and enhances the blood-brain transport of tryptophan, a precursor of serotonin. Furthermore, picolinic acid (a component of chromium picolinate) can alter serotonin, dopamine, and norepinephrine metabolism in the central nervous system (CNS).[17]

Research

Following a patient's report of "dramatic response to the addition of chromium supplementation to sertraline pharmacotherapy" for dysthymic disorder, McLeod et al.[60] conducted a set of single-blind and open-label trials in which they substituted other nutritional supplements in each of the patients to test the specificity of response to chromium supplementation. They described significant improvements in mood and "remission of dysthymic symptoms" in five patients being treated for antidepressant-refractory dysthymic disorder with sertraline who were coadministered chromium picolinate or chromium polynicotinate at dosage levels of 200 to 400 µg per day. The authors suggested further study through controlled trials; such research appears warranted.

In more recent research, Attenburrow et al.[17] examined the relationship of chromium to serotonin, particularly chromium picolinate's apparent effect of increasing the peripheral availability of tryptophan for brain serotonin (5-hydroxytryptamine,

5-HT) synthesis and altering the sensitivity of central 5-HT(2A) receptors. They compared the effects of short-term chromium administration on plasma concentrations of tryptophan and other large, neutral amino acids in human and animal models and assessed brain serotonin function by measuring the corticosterone/cortisol response to 5-hydroxytryptophan (5-HTP), the 5-HT precursor, which is hypothesized to be mediated via indirect activation of 5-HT(2A) receptors. These researchers observed that administration of chromium lowered the cortisol response to challenge with 5-HTP in both rats and humans. Changes in peripheral tryptophan availability were not seen in humans, but chromium increased peripheral and central tryptophan availability and elevated brain 5-HT content in rats.

Clinical Implications and Adaptations

Physicians prescribing SSRI medications for treatment of individuals diagnosed with depressive disorders are advised to evaluate potential therapeutic benefit on serotonin levels with concomitant administration of chromium, 200 µg once or twice daily. Integrative therapy combining chromium and antidepressants could prove efficacious, especially in patients with a history of hypoglycemia/dysglycemia, insulin resistance, or diabetes. Close monitoring and periodic reevaluation are necessary because gradual decreases in medication levels may be appropriate. Further research through well-designed, long-term clinical trials is warranted to investigate the implications of this potential synergy and guide formulation of therapeutic options.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Antacids, Histamine (H_2) Receptor Antagonists, and Proton Pump Inhibitors

Antacids: Aluminum carbonate gel (Basajel), aluminum hydroxide (Alternagel, Amphojel); combination drugs: aluminum hydroxide, magnesium carbonate, alginic acid, and sodium bicarbonate (Gaviscon Extra Strength Tablets, Gaviscon Regular Strength Liquid, Gaviscon Extra Strength Liquid); aluminum hydroxide and magnesium hydroxide (Advanced Formula Di-Gel Tablets, co-magaldrox, Di-Gel, Gelusil, Maalox, Maalox Plus, Mylanta, Wingel); aluminum hydroxide, magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); calcium carbonate (Titralac, Tums), magnesium hydroxide (Phillips' Milk of Magnesia MOM); combination drugs: magnesium hydroxide and calcium carbonate (Calcium Rich Rolaids); magnesium hydroxide, aluminum hydroxide, calcium carbonate, and simethicone (Tempo Tablets); magnesium trisilicate and aluminum hydroxide (Adcomag trisil, Foamicon); magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); combination drug: sodium bicarbonate, aspirin, and citric acid (Alka-Seltzer).

Histamine (H_2) receptor antagonists: Cimetidine (Tagamet; Tagamet HB), famotidine (Pepcid RPD, Pepcid, Pepcid AC), nizatidine (Axid, Axid AR), ranitidine (Zantac); combination drug: ranitidine, bismuth, and citrate (Tritec).

Proton pump inhibitors:

Evidence: Omeprazole (Losec, Prilosec).

Related: Esomeprazole (Nexium), lansoprazole (Prevacid, Zoton), pantoprazole (Protium, Protonix, Somac), rabeprazole (AcipHex, Pariet).

Antacids, H_2 blockers, and proton pump inhibitors (PPIs) may inhibit chromium absorption and could contribute to chromium depletion, particularly in susceptible populations. The mechanism(s) underlying this apparent interaction include altered pH levels, formation of insoluble complexes, or some combination but remain unclear.

Concomitant intake of calcium carbonate can interfere with the absorption of chromium. Seaborn and Stocker[61] used an isotope of chromium in male rats to measure potential interaction between calcium and chromium. Their findings indicate that calcium carbonate may result in reduced absorption and tissue retention of chromium. Notably, this experiment employed chromium chloride, known for poor absorption compared to other forms. Subsequently, a related research team using female rats observed that administration of antacid (40 mg) by gastric intubation (0.5 mL), followed orally by 55 µg Cr 51 chromium chloride, resulted in decreased chromium absorption.[20]

Evidence is lacking to substantiate extension of these preliminary findings to humans. However, chromium status is marginal in a large segment of the population, increasing the probability of this possible interaction being clinically relevant in some individuals. Thus it is advisable to recommend that oral intake of chromium be separated from administration of any antacid (including calcium carbonate) by 2 to 3 hours to reduce the risk of interfering with absorption. Further research is warranted through well-designed clinical trials of sufficient size and power.

Antipsychotics

Aripiprazole (Abilify, Abilitat), chlorpromazine (Largactil, Thorazine), clozapine (Clozaril), fluphenazine (Permitil, Prolixin, Prolixin Decanoate, Prolixin Enanthate), haloperidol (Haldol), olanzapine (Zyprexa), prochlorperazine (Compazine, Stemetil), quetiapine (Seroquel), risperidone (Risperdal), ziprasidone (Geodon).

An interaction between chromium and antipsychotic medications is theoretically plausible, but no substantive evidence from case reports or clinical trials has emerged to confirm (or refute) this occurrence or articulate its clinical implications. Directly, and through its effects on insulin, chromium influences several neurotransmitters. Notably, insulin inhibits the reuptake of norepinephrine and enhances the blood-brain transport of tryptophan, a precursor of serotonin. Furthermore, picolinic acid, a component of chromium picolinate, is known to alter serotonin, dopamine, and norepinephrine metabolism in the CNS. Prudence suggests that, pending further research, the concomitant use of chromium preparations and antipsychotic medications should be avoided outside the context of supervision of health care professionals trained and experienced in both conventional psychopharmacology and nutritional therapeutics.

Lithium Carbonate

Lithium carbonate (Camcolit, Carbolith, Duralith, Eskalith, Li-Liquid, Liskonum, Litarex, Lithane, Lithobid, Lithonate, Lithotabs, PMS-Lithium, Priadel).

Lithium carbonate has been found to reduce blood glucose levels in diabetic individuals. Chromium potentiates the action of insulin. The combined effect of two substances with potential hypoglycemic action might present a significant risk for excessively low blood glucose levels.[62]

Chromium's ability to enhance endogenous regulation of blood glucose levels, together with its potentiation of insulin, make it a valuable tool in stabilizing diabetic physiology and

eventually reducing dependence on insulin. Physicians prescribing lithium are advised to ask patients if they are taking or have been considering use of chromium supplementation. Such coadministration might be efficacious but requires close monitoring of blood glucose levels, especially in individuals with a history of hypoglycemia or in the presence of insulin/oral sulfonylurea therapy. Health care professionals experienced in nutritional therapeutics typically prescribe chromium at a dosage of 200 µg once or twice daily; chromium picolinate or histidine is the preferred form.

Meperidine

Meperidine (Demerol).

Tyramine intake may result in adverse effects in individuals taking meperidine (which has a lethal interaction with classic MAO inhibitor antidepressants). Brewer's yeast contains a significant amount of tyramine and thus should be considered a potentially harmful or serious adverse interaction.

It is highly improbable that the amount of tyramine contained in yeast-based chromium preparations is adequate to result in an adverse event, particularly at usual dosage levels. Nevertheless, physicians prescribing meperidine should advise patients to avoid significant intake of yeast, including chromium supplements containing yeast. Forms of chromium not derived from or containing yeast do not carry this potential risk.

Monoamine Oxidase (MAO) Inhibitors

MAO-A inhibitors: Isocarboxazid (Marplan), moclobemide (Aurorix, Manerix), phenelzine (Nardil), procarbazine (Matulane), tranylcypromine (Parnate).

MAO-B inhibitors: Selegiline (deprenyl, L-deprenil, L-deprenyl; Atapryl, Carbex, Eldepryl, Jumex, Movergan, Selpak), pargyline (Eutonyl), rasagiline (Azilect).

Tyramine intake will often result in adverse effects in individuals taking MAO inhibitors. Brewer's yeast contains a significant amount of tyramine and thus should be considered as potentially harmful or serious adverse interaction.

It is highly improbable that the amount of tyramine contained in yeast-based chromium preparations is adequate to result in an adverse event, particularly at usual dosage levels. In a 1984 survey and critical review of the literature on the subject of diet and MAO inhibitors, Sullivan and Shulman[63] determined that "only four foods clearly warrant absolute prohibition: aged cheese, pickled fish (herring), concentrated yeast extracts and broad bean pods." Nevertheless, physicians prescribing MAO inhibitors should advise patients to avoid significant intake of yeast, including chromium supplements containing yeast. Forms of chromium not derived from or containing yeast do not carry this potential risk.

Nicotinic Acid (Vitamin B_3)

Nicotinic Acid (Vitamin B_3)

A potential interaction between chromium and nicotinic acid has been discussed, but only preliminary evidence is available as to its clinical implications. Nicotinic acid serves as substrate for synthesis of GTF, which is believed to facilitate insulin binding. Concomitant intake may improve glucose tolerance, particularly in individuals whose diet provides inadequate levels of dietary nicotinic acid. Consequently, inadvertent, excessive, or unsupervised coadministration might theoretically induce a hypoglycemic state. This largely unexplored territory is further confounded by the possibility that niacin may cause insulin resistance.

Urberg and Zemel[64] conducted an experiment in which 16 healthy elderly volunteers were divided into three groups and given either 200 µg chromium chloride, 100 mg nicotinic acid, or 200 µg chromium plus 100 mg nicotinic acid daily for 28 days, with evaluations on days 0 and 28. They observed the combined chromium–nicotinic acid supplement caused a 15% decrease in a glucose area integrated total and a 7% decrease in fasting glucose, whereas chromium or nicotinic acid alone did not affect fasting glucose or glucose tolerance. None of the interventions exerted any significant effect on fasting or 1-hour insulin levels. These researchers interpreted their findings to suggest that the inability to respond to chromium administration may result from suboptimal levels of dietary nicotinic acid. These findings also raise the question as to whether, as analogs, picolinate and nicotinate may share the same transport system for intestinal absorption, and if so, picolinate could then block nicotinate absorption, and vice versa.

Individuals who do not respond to administration of chromium may have inadequate levels of vitamin B_3. Coadministration may be beneficial. Patient caution, and possibly supervision by a health care professional trained and experienced in nutritional therapeutics, may be appropriate in the unlikely event (in the absence of prescription antidiabetic medication) that such intervention induces hypoglycemia.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

COX-1 inhibitors: Diclofenac (Cataflam, Voltaren); combination drug: diclofenac and misoprostol (Arthrotec); diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), flurbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen); combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen); indomethacin (indometacin; Indocin, Indocin-SR), ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Aleve, Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).

COX-2 inhibitor: Celecoxib (Celebrex).

The NSAIDs may increase chromium levels in the body by enhancing chromium absorption from oral intake while also delaying or inhibiting chromium elimination. In a rat model, indomethacin and aspirin have been shown to increase chromium absorption.[61] Evidence is lacking to substantiate these proposed actions, and no case reports or clinical trials have documented clinically significant adverse effects.

NUTRIENT-NUTRIENT INTERACTIONS

Biotin

Chromium picolinate and biotin appear to work together to enhance glucose uptake in skeletal muscle cells and improve glucose disposal. Singer and Geohas[64a] conducted a placebo-controlled, double-blind, randomized trial investigating the effects on glycemic control of coadministering chromium and biotin in 43 type 2 diabetic subjects who were "poorly controlled" by oral antihyperglycemic agents. They coadminstered chromium picolinate (600 µg) and biotin (2 mg) daily, in addition to their prestudy oral antihyperglycemic agent therapy. After 4 weeks, they observed "a significantly greater reduction

in the total area under the curve for glucose" during the 2-hour oral glucose tolerance test for the treatment group compared with the placebo group, along with "significantly greater reductions" in fructosamine, triglycerides, and triglycerides/HDL cholesterol ratio in the treatment group. The authors concluded that coadministration of chromium picolinate and biotin "may represent an effective adjunctive nutritional therapy to people with poorly controlled diabetes with the potential for improving lipid metabolism." These findings indicate the need for continued research into the use of multiple nutritional interventions as complements to conventional pharmacological interventions within a broad and multifaceted, individualized and evolving strategic approach to dysglycemia and diabetes.

Calcium

The concomitant intake of calcium carbonate and chromium can interfere with the absorption of both agents and thus reduce the activity of chromium intake.[65] Optimal absorption can be maintained by separating intake of the two substances by at least 2 hours.

Further research is warranted to determine whether, and to what degree, the observed effect is caused by the antacid effect of calcium carbonate, or could be specific to calcium per se.

Carbohydrates

Excessive intake of sugars and other simple carbohydrates may increase the amount of chromium excreted through the urine.

In a 12-week trial, Kozlovsky et al.[66] compared chromium excretion in 37 subjects fed two diets containing equivalent chromium content, approximately 16 µg per 1000 calories. During the initial 6 weeks, the reference diet contained "optimal levels" of protein, fat, carbohydrate, and other nutrients, with 35% of total calories from complex carbohydrates and 15% from simple sugars. During the following 6 weeks, subjects consumed "high sugar diets" containing 15% complex carbohydrates and 35% simple sugars. During the high-sugar diets, subjects exhibited increased urinary chromium losses from 10% to 300% for 27 of 37 subjects, compared with the reference diets. The authors contextualized this significant stimulation of chromium loss associated with the high-sugar diet by further noting that "marginal intake of dietary Cr may lead to marginal Cr deficiency, which is associated with impaired glucose and lipid metabolism."

Using a mouse model, Seaborn and Stoecker[67] demonstrated that the source of carbohydrate can alter chromium absorption and retention. All animals were fed a diet in which 50% was composed of starch, sucrose, fructose, or glucose and compared with those fed a low-chromium diet and those administered 1 mg/kg chromium in the form of chromium chloride, a large dose. After 26 days they found that chromium concentrations were significantly higher in testes, spleen, kidney, and liver, as well as blood, epididymal fat pad, and femur, of animals given their carbohydrate load as starch than in animals fed sucrose, fructose, or glucose. Furthermore, elevated bone and kidney chromium concentrations and heart and muscle glycogen were associated with chromium administration.

In a small clinical trial, Anderson et al.[68] administered five different carbohydrate-based drinks to 20 subjects in amounts corresponding to body weight. They found that glucose plus fructose was the most insulinogenic, followed by glucose alone, starch plus fructose, starch alone, and water plus fructose. Furthermore, they observed that subjects with the highest concentrations of circulating insulin displayed decreased ability to mobilize chromium on the basis of urinary chromium excretion. These researchers concluded that such urinary chromium losses parallel the insulinogenic properties of carbohydrates.

Urinary chromium excretion is greater in adults with diets high in simple sugars (e.g., sucrose) than in those with diets high in complex carbohydrates (e.g., whole grains). Increased insulin secretion in response to the consumption of simple sugars (vs. complex carbohydrates) appears to contribute significantly to this effect.[68-71] Decreased chromium intake and potentially compromised chromium status are also strongly associated with diets higher in simple carbohydrates and refined foods.

Chromium, 200 µg once or twice daily, may be beneficial in individuals with dietary intake high in sugars and simple carbohydrates. A dietary approach emphasizing lean meats, healthy fats and oils, carbohydrate sources low on the glycemic index (especially nutrient-rich fruits, vegetables, and whole grains), and a minimum of processed foods and refined carbohydrates will enhance the action and retention of dietary and supplemental chromium support for healthy insulin function and reduce the risk of dysglycemia, obesity, diabetes, and cardiovascular disease.[72]

Hydroxycitric Acid

See *Gymnema sylvestre*.

Iron

Chromium and iron compete for binding on transferrin, the iron transport protein. Thus, excessive levels of either mineral can interfere with transport of the other.

In an 8-week placebo-controlled study of younger men doing resistance training, Lukaski et al.[73] observed an insignificant decrease in transferrin saturation with iron after administration of 200 µg of chromium daily (3.3-3.5 µmol as chromium chloride or chromium picolinate). In a similar randomized, double-blind, placebo-controlled trial involving 18 older men (age 56-69) engaged in resistive training twice weekly, Campbell et al.[74] found that 925 µg of chromium picolinate daily for 12 weeks did not significantly affect hematologic indices, measures of iron metabolism, or iron status. Based on these and related findings, it has also been hypothesized that decreased chromium transport might contribute to the diabetes associated with hereditary hemochromatosis.

Well-designed long-term studies have yet to be published investigating this interaction more thoroughly.

Vanadium

Evidence from in vitro and in vivo research has been accumulating for more than 20 years showing that vanadyl and vanadate (i.e., vanadium salts) mimic insulin action in isolated cell systems and lower glucose levels in diabetic animals. Diabetic patients administered vanadium salts, containing 25 to 100 mg of elemental vanadium, daily for up to 6 weeks have demonstrated partial normalization of glucose metabolic irregularities.[75-78]

Human trials investigating the potential synergy between chromium and vanadium are warranted. Pending such clarification, professional supervision is appropriate for individuals with diabetes who choose to undertake such therapies, especially within the context of conventional therapy using insulin or oral hypoglycemic medications.

Vitamin C

Concomitant intake of vitamin C may increase chromium absorption. Animal research has shown that simultaneous intake of chromium and vitamin C enhances chromium uptake.[79] Seaborn et al.[80] studied the effects of chromium and ascorbate depletion in a guinea pig model and observed a synergistic relationship between ascorbic acid and chromium. They noted that their "findings suggest that dietary Cr may affect ascorbic acid metabolism and the metabolic response to stress."

A healthy intake of both chromium and vitamin C can play a role in the prevention and treatment of dysglycemia, lipid disorders, and cardiovascular disease.

Theoretically, an excess of chromium might result if a high intake was accompanied by high doses of vitamin C. The clinical significance of any potentially adverse effect is improbable, whereas the potential benefits of a synergistic interaction between these nutrients is plausible, even probable, at appropriate dosage levels in most individuals, particularly those with compromised dietary intake.

In vitro experiments have consistently found that the addition of ascorbic acid to plasma containing chromium(VI) leads to a dose-dependent reduction of chromium(VI) to chromium(III).

Zinc

Data from animal research indicate that coadministration of zinc and chromium may reduce intestinal content and absorption of zinc, particularly in the presence of zinc deficiency.[81] Pending further research, separating intake of these two minerals by at least several hours may be advisable to enhance absorption.

HERB-NUTRIENT INTERACTIONS

Gymnema sylvestre

Gymnema sylvestre, a plant native to the tropical forests of India, has played a role in the Ayurvedic treatment of diabetes for centuries. It has been postulated that *Gymnema* enhances the production of endogenous insulin. A typical dosage of *G. sylvestre* extract is 400 to 600 mg per day.

In a randomized, double-blind, placebo-controlled clinical trial, Preuss et al.[82] compared the effects of (+)-hydroxycitric acid alone and in combination with niacin-bound chromium and a standardized *G. sylvestre* extract in 60 moderately obese subjects over 8 weeks. Both groups receiving *Gymnema* demonstrated 5% to 6% reductions in body weight as well as significant reductions in food intake, total cholesterol, LDLs, triglycerides, and serum leptin levels, compared with those receiving placebo; HDL levels and excretion of urinary fat metabolites increased in both treated groups. The authors concluded that optimal doses of (−)-hydroxycitric acid and, to a greater degree, the combination of (−)-hydroxycitric acid, niacin-bound chromium, and *G. sylvestre* extract can serve as an effective and safe weight loss formula that can facilitate a reduction in excess body weight and BMI while promoting healthy blood lipid levels.

The 84 citations for this monograph, as well as additional reference literature, are located under Chromium on the CD at the back of the book.

Copper

Nutrient Name: Copper.
Synonyms: Copper carbonate, copper citrate, copper gluconate, copper glycinate, copper lysinate, copper sebacate, copper sulfate, cupric acetate, cupric oxide; cuprum.
Elemental Symbol: Cu.
Related Substance: Chlorophyllin.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Allopurinol ≈◇◇/☼	Allopurinol, a potent inhibitor of xanthine oxidase, forms a complex with copper that can reduce cardiac damage, which appears to be due to copper- and ascorbate-mediated DNA breakage, in patients undergoing cardiac bypass surgery. The mechanisms involved are not fully understood, but the resulting complex exhibits low redox activity.	Chelation of copper by allopurinol may help protect against cardiac damage during reperfusion of the heart. Avoid copper before bypass surgery.
Antacids ≈≈≈	Antacids can inhibit copper absorption and induce intestinal alkaline pH, which can precipitate dietary copper. Copper depletion and deficiency may result from excessive or extended use of antacids, especially with pyloric stenosis. Mechanism reasonable, but clinically significant adverse effects probably infrequent.	Coadminister with extended antacid use.
Cimetidine ✗✗/◇	Animal studies indicate cimetidine complexes with Cu(II) and Fe(III) ions and may elevate tissue copper concentrations, particularly in the liver. By binding copper (and iron), cimetidine may also act as a free-radical scavenger. Although the proposed mechanisms are plausible, evidence remains preliminary.	Coadminister if indicated. Separate intake by at least 2 hours.
Ciprofloxacin ◇◇	Copper and other minerals can bind to ciprofloxacin and reduce its absorption. Copper evidence preliminary, but parallel phenomenon with iron generally recognized. Drug efficacy could be impaired.	Separate intake by at least 2 hours.
Clofibrate fibrates ≈≈≈/⊕✗/◇◇/?	Clofibrate may enhance copper metabolism and elevate hepatic copper levels, and may reduce hypercholesterolemia, particularly with compromised copper status. Research is limited, with mixed findings and conclusions.	Coadminister, as appropriate; monitor.
Ethambutol ☼/◇≈≈/⊕⊕	Ethambutol forms chelate complexes with copper (and zinc), which may contribute to drug-induced optic neuropathy.	Coadminister and monitor visual function. Separate intake by at least 2 hours.
Famotidine H_2 receptor antagonists (H_2RAs) ≈≈≈	Famotidine and H_2RAs interfere with the acidic gastric environment optimal for copper absorption. Such drug-induced changes can inhibit copper absorption and induce alkaline intestinal pH, which can precipitate dietary copper. Subsequent copper depletion and deficiency may result from excessive or extended gastric acid–suppressive therapy. Mechanism reasonable but frequency of clinically significant adverse effects unknown.	Coadminister with extended H_2RA use. Separate intake by at least 2 hours.
Nonsteroidal anti-inflammatory drugs (NSAIDs) ☼/⊕	Copper tends to complex with NSAIDs and might enhance their anti-inflammatory effects while reducing their ulcerogenic effects. Evidence preliminary and promising, but mixed; clinical implications likely significant.	Consider coadministration.
Oral contraceptives (OCs) Estrogens/progestins Hormone replacement therapy (HRT) ◇◇	Exogenous female hormones, especially progestins, may enhance copper absorption and elevate copper levels. Clinical significance may vary with age, specific medication, and other factors and could contribute to increased adverse drug effects, e.g., cardiovascular risk.	Avoid concomitant copper supplementation unless risk of depletion or other prevailing benefits.
Penicillamine, trientine, and tetrathiomolybdate Chelating agents ◇◇/≈◇◇	These chelating agents are designed to bind copper and limit its absorption and accumulation, particularly in treatment of mineral deposition disorders such as Wilson's disease and increasingly in antiangiogenic cancer therapy. Interaction is purposeful, and its clinical significance is generally recognized.	Limit dietary and avoid supplemental copper intake. Monitor for adverse drug effects.
Valproic acid Anticonvulsant medications ≈≈/◇≈≈	Valproic acid and related antiepileptics may induce copper deficiency and disrupt copper homeostasis by increasing excretion into bile. Preliminary evidence of depletion pattern; prevalence uncertain. Possible risk of clinical significance primarily with long-term anticonvulsant therapy.	Monitor copper (and zinc) status. Copper administrator warranted with deficiency indications or other risk factors.
Zidovudine (AZT) Reverse-transcriptase inhibitor (nucleoside) antiretroviral agents ≈≈/⊕/☼/◇	Coadministration of zinc with AZT can reduce adverse effects and enhance efficacy but extended therapy requires complement of copper to prevent adverse effects from zinc, thus providing a more comprehensive approach to supporting patients on AZT. Evidence preliminary, clinical significance unconfirmed.	Coadminister copper with extended zinc use.

NUTRIENT DESCRIPTION

Chemistry and Forms

Copper carbonate, copper citrate, copper gluconate, copper glycinate, copper lysinate, copper sebacate, copper sulfate; copper amino acid chelates; cupric acetate, cupric oxide.

Physiology and Function

Copper is an essential trace mineral that is present in all tissues and acts as a cofactor in several key enzyme systems. The average adult body contains about 80 to 120 milligrams of copper, most of which is stored in the liver. Copper stimulates iron absorption and is an important catalyst in hemoglobin synthesis and function. Copper is necessary to make adenosine triphosphate (ATP) and acts as an essential component of cytochrome oxidase, which is necessary for energy metabolism, cellular respiration, and myelin formation.

Copper is involved in the synthesis and breakdown of several hormones. Copper serves as a cofactor in dopamine–β-hydroxylase, which oxidizes ascorbic acid and synthesizes norepinephrine. It is also involved in the catabolism of estrogenic hormones. Copper may play a role in emotional regulation and cognitive function.

Copper is absorbed in the small intestine, where it is transferred across the gut wall by albumin, and carried on transcuprein and albumin to the liver, where it is incorporated into liver enzymes and secreted into the blood on the protein ceruloplasmin. Copper absorption has been found to be greater in women (71%) than in men (64%), age 20 to 59 years, but did not differ in men and women 60 to 83 years old. Copper elimination is primarily via bile, with small amounts eliminated in urine, sweat, and epidermal shedding.

Copper plays a central role in decreasing inflammation through both ceruloplasmin and the copper-containing form of superoxide dismutase (SOD). *Ceruloplasmin* is a weak, broad-specificity oxidase whose main functions include copper transport and extracellular scavenging of superoxide and other oxygen radicals. Adequate ceruloplasmin levels also minimize copper toxicity by limiting absorption of copper. Copper, along with zinc, as well as manganese, is found in cytostolic SOD. SOD is a primary quencher of superoxide radical, a prevalent and highly reactive free-radical form of oxygen produced during oxidative phosphorylation, which can be quite destructive if not rapidly quenched. SOD slows age-related deterioration, protects against chemical sensitivities (along with polyphenol oxidase), and enables the normal humoral immune response. There are also copper-containing amino acid chelates that have SOD activity. During inflammatory conditions, such as acute infections, serum copper levels, as ceruloplasmin, generally increase by 20% to 30%, whereas serum iron levels decline. Plasma copper, enzymatic ceruloplasmin, and immunoreactive (RID) ceruloplasmin have been observed to be significantly higher in women than in men, but SOD and in vitro ^{67}Cu uptake by red blood cells does not appear to differ between the genders.

Histaminase, which breaks down histamine to control allergies and inflammation, is another copper-dependent enzyme involved in regulating inflammatory processes. *Tyrosinase*, an enzyme that requires copper, plays a role in melanin synthesis, enabling skin pigmentation and hair coloration, as well as keratinization of hair.

Some researchers have proposed that copper deficiency is associated with elevated cholesterol and triglycerides, the development of atherosclerosis, and increased risk of cardiovascular disease.

Copper functions in the synthesis of collagen and repair of connective tissue, providing structural elasticity not only throughout the musculoskeletal system, but also in tissues of the lungs, blood vessels, and skin. Lysil oxidase, a copper-containing enzyme secreted by connective tissue cells, is necessary for the formation of the cross-links of collagen and elastin.

Copper is an essential element and its level in the body is strictly controlled. Under most conditions, excess copper is excreted in the urine and feces (via the bile). In cases of elevated copper, the adverse effects that develop are often caused less directly by copper toxicity than by its interference with the absorption and distribution of other mineral nutrients, such as iron and zinc.

Copper sulfate, cupric acetate, and alkaline copper carbonate are among the forms of copper best absorbed in the gut. Nevertheless, even though animal studies have demonstrated that it is poorly absorbed in the gut, *cupric oxide* (CuO) is the form of copper most often used in over-the-counter (OTC) preparations. *Chloropíhllin* is a relatively new, water-soluble copper complex of chlorophyll.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Copper has been proposed as offering therapeutic benefit in a wide range of conditions. Such therapeutic action has largely been premised on the hypothesis that administration will enhance or restore healthy function in the numerous enzyme systems where copper plays a critical role. Nevertheless, direct evidence confirming copper's efficacy in treating most of the diseases proposed is largely lacking, other than to prevent or treat those directly attributable to, or exacerbated by, copper deficiency or depletion.

Historical/Ethnomedicine Precedent: As the classical metal of Venus, copper was associated with the female reproductive system in ancient times.

Possible Uses

Anemia, aneurysms, atherosclerosis, athletic performance, benign prostatic hyperplasia, burns, cardiac arrhythmia, cardiovascular disease, decubitus ulcers, hypercholesterolemia, hypoglycemia, immune enhancement, Menkes' syndrome, muscle spasms, osteoporosis, peptic ulcer, peripheral vascular disease, rheumatoid arthritis, skin cancer (prevention), sprains and strains, stomach cancer (prevention), vitiligo, wound healing.

Deficiency Symptoms

Most research into copper deficiency has focused on acute, severe deficiency. Such frank clinical copper deficiency is relatively rare in humans and animals on typical, varied diets. However, marginal, chronic deficiency is not uncommon. Dietary surveys indicate that the average dietary intake of copper in the U.S. population is only half of the recently established recommended dietary allowance (RDA). Most cases of copper deficiency involve premature infants, infants suffering from malnutrition, or children with iron deficiency anemia, severe protein malnutrition, chronic diarrhea, or other malabsorption difficulties. Overt symptoms in adults are rare but may occur with inadequate or

unbalanced dietary intake over an extended time or in those who consume zinc supplements chronically without counterbalancing copper. The determination of copper needs and marginal deficiency is obscured because copper deficiency may not manifest as decreased levels of copper-dependent enzymes, but it may still significantly lower their activity.

Because copper is required for a wide range of enzyme systems and metabolic processes, a deficiency can cause a variety of disorders. Laboratory animals fed copper-deficient diets tend to develop anemia, cardiac abnormalities and abnormal electrocardiograms, and elevated levels of serum cholesterol, triglycerides, and glucose. Symptoms of copper deficiency in humans include fatigue, hypotonia, hypothermia, growth retardation, reduced resistance to infection, various nervous system disorders, anemia, neutropenia, degeneration of vasculature, cardiac damage, hemolysis with potential liver and brain damage, various cardiovascular problems, impaired respiration, emphysema, elevated low-density lipoprotein (LDL) cholesterol and reduced high-density lipoprotein (HDL) cholesterol, impaired collagen formation, breakdown of connective tissue, bone demineralization, osteoporosis, depigmentation of skin, and changes in structure and appearance of hair.

Genetic Conditions Relating to Copper

Two primary genetic diseases involve copper metabolism: Menkes' syndrome and Wilson's disease.

Menkes' syndrome results from an X-linked mutation of genes encoding Cu-binding P-type adenosinetriphosphatase (ATPase) for the efflux of Cu, ATP7A. Apart from the distinctive kinky or steely hair, this syndrome is also characterized by stunted growth, abnormalities in cardiovascular and skeletal development, progressive cognitive decline, and premature death. This inborn error in metabolism limits absorption of copper in the intestines and uptake in the liver. Copper subsequently accumulates in the intestinal cells and produces symptoms resembling copper deficiency.

Wilson's disease, caused by the mutation of genes encoding Cu-binding ATPase for the efflux of Cu, ATP7B, is characterized by accumulation of copper in the liver, leading to severe hepatic damage; elevated copper levels subsequently affect the brain and result in neurological problems.

Dietary Sources

Oysters are the most abundant food source of copper. Other copper-containing foods include soy, peas, and other dried legumes; dark-green leafy vegetables; whole-grain breads and cereals; seafood, including crab and lobster; lamb, pork, and other meats, especially organ meats such as liver; nuts (almonds, pecans, walnuts); raisins, prunes, and pomegranates; and tea, coffee, and chocolate.

Foods rich in copper are generally also rich in iron.

Nutrient Preparations Available

Copper sulfate, cupric acetate, cupric oxide, and alkaline copper carbonate. As previously noted, CuO is the form most often used in OTC preparations, primarily because of its low cost. Chlorophyllin is a copper complex of chlorophyll.

Copper is usually found in multimineral or multivitamin/multimineral formulations.

Copper is often taken with, although preferably ingested apart from, long-term zinc administration to counteract the tendency to copper depletion associated with zinc intake without copper. Recommended Zn/Cu ratio in formulations is 10:1 to 15:1.

Dosage Forms Available

Capsule, tablet; cupric sulfate: injection (U.S.).

Dosage Range

Adult

Dietary: 1.0 to 1.5 mg/day
Supplemental/Maintenance: 1 to 2 mg/day
Pharmacological/Therapeutic: 2+ mg/day

Pharmacological doses of copper in scientific studies usually range from 2 to 4 mg per day. Copper dose is usually based on zinc intake. Many experts consider the optimal zinc/copper ratio as 10:1. Some practitioners of nutritional therapeutics use zinc at dosages up to 45 mg/day as part of therapeutic protocols. In such cases, LDL and HDL cholesterol levels need to be monitored. Zinc may need to be reduced or copper increased; even so, doses of copper greater than 3 mg/day are usually avoided.

Pediatric (<18 Years)

Supplemental/Maintenance: 0.5 to 1.0 mg/day
Pharmacological/Therapeutic: 1 to 2 mg/day

Laboratory Values

Serum ceruloplasmin concentrations and white blood cell (WBC) levels have been considered the most reliable methods of evaluation but often are insensitive to subtle changes in copper status. Copper-containing enzymes, such as Cu-Zn SOD, cytochrome-*c* oxidase, and diamine oxidase, may be more reliable, but evidence to date is not conclusive.[1] LDL and HDL cholesterol levels are sometimes used.

Serum, plasma, urinary, or hair copper concentrations are not considered particularly reliable because these monitoring parameters are subject to many variables and may not accurately demonstrate actual copper load; when used, such determinations are recommended monthly.

SAFETY PROFILE

Overview

Copper is generally considered safe when taken at customary dietary or typical supplemental dosage levels. Chronic copper toxicity from intentional intake in adults is rare. Long-term doses of 10 to 35 mg per day are considered safe. The tolerable upper limit (UL) of copper intake established by the U.S. National Institute of Medicine for adults is 10 mg per day, combining dietary and supplemental sources. However, research has suggested that the body cannot eliminate more than 3 mg/day, so in individuals who are copper replete or overloaded, greater than 3 mg/day dietary copper may contribute to further accumulation.

Nutrient Adverse Effects

General Adverse Effects

In adults, 10 mg of copper daily can induce nausea, and 60 mg may cause vomiting. Tissue elevations usually occur only when intake is 300 to 500 times above normal. The adverse effects

on zinc metabolism represent the primary adverse effect of excessive copper levels.

Mutagenicity

No human data are available. Results from short-term tests on mutagenicity have been negative or inconclusive.

Adverse Effects Among Specific Populations

Copper intake exerts particular risk for individuals with Wilson's disease, a genetic disorder that causes a toxic accumulation of copper in the liver, kidneys, central nervous system (CNS), and cornea. Maximum safe daily dosages of copper intake for individuals with severe liver or kidney disease are of concern but have not been determined. Copper toxicity has occasionally been reported in individuals living in houses where copper from water pipes has leached into the drinking water.

Pregnancy and Nursing

Maximum safe daily dosages of copper intake for pregnant or nursing women have not been determined. There are no reports in the literature reviewed of teratogenicity or embryotoxicity in humans induced by excess copper intake. However, animal studies indicate that a deficiency or excess of copper in the body can cause significant harm to developing embryos.

Infants and Children

Maximum safe daily dosages of copper intake for infants and young children have not been determined. Copper can exert a lethal dose in children at levels as low as 3.5 g. The copper (and zinc) status of epileptic children taking valproate derivatives should be monitored.

Toxicity Signs and Symptoms

Symptoms of moderate copper toxicity include weakness, dizziness, fainting, headache (severe or continuing), burning sensation in the throat, gastrointestinal disturbances, loss of appetite, vomiting, excess salivation, metallic taste in mouth, dyspepsia, epigastric pain, painful urination, and low back pain. Severe cases can result in hemolytic anemia, hypertension, liver damage, jaundice, hemochromatosis, hemoglobinuria, hematuria, kidney failure, coma, and death. O'Donohue et al.[2] reported a case of adult chronic copper self-intoxication, after daily doses of 30 to 60 mg for 3 years, which resulted in severe liver cirrhosis necessitating orthotopic liver transplantation.

Contraindications

Biliary disease, cancer, heart bypass patients, liver disease, migraines, Wilson's disease. Copper is also contraindicated during the course of anticopper therapies. Some individuals may have a total body excess of copper resulting from a lifetime of drinking water from copper plumbing, and copper supplementation may not be desirable in such people.

Precautions and Warnings

Some individuals may become sensitized to copper sulfate and develop allergic contact dermatitis.

INTERACTIONS REVIEW

Strategic Considerations

Many medications may deplete copper or interfere with its metabolic functions, sometimes incidentally, but often intentionally. Copper supplementation may be appropriate to correct drug-induced depletion patterns. In certain cases, however, such action is central to the therapeutic strategy, and supplementation is contraindicated, except in response to specific episodes of adverse effects of excessive copper deficiency caused by depletion. Conversely, in some situations, drugs such as allopurinol may provide benefit by reducing copper levels.

NUTRIENT-DRUG INTERACTIONS

Allopurinol

Allopurinol (Oxypurinol; Aloprim, Apo-Allopurinol, Lopurin, Purinol, Zyloprim).

Interaction Type and Significance

≈◇◇ **Drug-Induced Nutrient Depletion, Supplementation Contraindicated, Professional Management Appropriate**

☼ **Prevention or Reduction of Nutrient Adverse Effect**

Probability:
2. Probable

Evidence Base:
○ Preliminary

Effect and Mechanism of Action

Allopurinol, a potent inhibitor of xanthine oxidase, is known to protect the heart effectively against damage in patients undergoing cardiac bypass surgery. Nevertheless, the mechanism underlying the protective effect of allopurinol is unclear because of ambiguity concerning the presence of xanthine oxidase in the human heart. Allopurinol apparently chelates copper and reduces DNA breakage (see next).

Research

In 1993, Malkiel et al.[3] published a paper examining the possible role of the interaction between allopurinol and copper in myocardial protection. They found that allopurinol forms a one-to-one complex with Cu(II) ions in vitro, yielding a complex with low oxidation-reduction (redox) activity, and concluded that allopurinol substantially reduced copper-mediated and ascorbate-driven DNA breakage. Later research by Lapenna et al.[4] found that allopurinol, at therapeutically relevant concentrations (9-58 μM), significantly counteracted copper-catalyzed human non–HDL lipoprotein oxidation through metal complexation.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The ability of allopurinol to chelate copper may impart the protective effects against cardiac damage in bypass patients during reperfusion of the heart. These findings suggest that patients undergoing bypass surgery should avoid copper supplementation.

Antacids

Aluminum carbonate gel (Basajel), aluminum hydroxide (Alternagel, Amphojel); combination drugs: aluminum hydroxide, magnesium carbonate, alginic acid, and sodium bicarbonate (Gaviscon Extra Strength Tablets, Gaviscon Regular Strength Liquid, Gaviscon Extra Strength Liquid); aluminum hydroxide and magnesium hydroxide (Advanced Formula Di-Gel Tablets, co-magaldrox, Di-Gel, Gelusil, Maalox, Maalox Plus, Mylanta, Wingel); aluminum hydroxide, magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); calcium

carbonate (Titralac, Tums), magnesium hydroxide (Phillips' Milk of Magnesia MOM); combination drugs: magnesium hydroxide and calcium carbonate (Calcium Rich Rolaids); magnesium hydroxide, aluminum hydroxide, calcium carbonate, and simethicone (Tempo Tablets); magnesium trisilicate and aluminum hydroxide (Adcomag trisil, Foamicon); magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); combination drug: sodium bicarbonate, aspirin, and citric acid (Alka-Seltzer).
See also Cimetidine and Famotidine.

Interaction Type and Significance
≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **3. Possible:**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action
The normally acidic environment of the stomach facilitates optimal absorption of copper and other nutrients. Antacids may induce a copper deficiency by inhibiting copper absorption and precipitating dietary copper through drug-induced alkaline pH in the intestines.

Reports
Roe, van Kalmthout, and other authors have reported cases where individuals have demonstrated the effects of copper deficiency subsequent to excessive use of antacids.[5-9] Such outcomes may appear to be more likely with extended use of antacids and the occurrence of pyloric stenosis.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Clinically significant adverse effects from antacids reducing copper absorption appear to occur infrequently. Nevertheless, individuals who take antacids for an extended period may benefit from 1 to 2 mg of copper supplementation daily, possibly in the form of a multivitamin/mineral formula.

Cimetidine

Cimetidine (Tagamet; Tagemet HB)

Interaction Type and Significance
✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**
◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **4. Plausible**
Evidence Base: ○ **Preliminary**
See also Antacids and Famotidine.

Effect and Mechanism of Action
Cimetidine complexes with Cu(II) and Fe(III) ions and may elevate tissue copper concentrations.

Research
The considerations regarding this interaction derive from research involving rats. Naveh et al.[10] published a paper in 1987 that described elevated hepatic and plasma copper concentrations, mineral redistribution, and pathological changes in some tissues after intermediate to high doses of cimetidine (875-1750 mg/kg/day) administered intragastrically to young rats four times weekly for 5 weeks. More recent research by Lambat et al.[11] and others has focused on the action of cimetidine as a free-radical scavenger and neuroprotective agent through its ability to bind to iron and copper, thus making them unavailable for free-radical production.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Given the consistent evidence of cimetidine's mineral-binding properties, individuals taking copper supplements are advised to allow at least a 2-hour interval after taking cimetidine to avoid diminished therapeutic effect from the nutrient. The therapeutically appropriate level copper supplementation would be in the range of 1 to 2 mg/day.

Ciprofloxacin

Ciprofloxacin (Ciloxan, Cipro)

Interaction Type and Significance
◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

Probability: **2. Probable**
Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action
Minerals, including copper, can bind to ciprofloxacin, greatly reducing the absorption of the medication.

Research
The formation of a ferric ion–ciprofloxacin complex is a well-documented cause of the reduction in ciprofloxacin bioavailability in the presence of iron.[12-14] Complexation between Cu(II) and 4-quinolone antibacterials, including ciprofloxacin, has been studied in an aqueous medium.

Clinical Implications and Adaptations
Even though not as severe as with iron supplements, the tendency for copper and other minerals to bind ciprofloxacin suggests that individuals taking this and related antibacterial medications can reduce the risk of interfering with the drug's therapeutic effect by allowing at least a 2-hour interval after ingesting any copper or multimineral supplement.

Clofibrate and Related Fibrates

Evidence: Clofibrate (Atromid-S).
Extrapolated, based on similar properties: Bezafibrate (Bezalip), ciprofibrate (Modalim), fenofibrate (Lofibra, Tricor, Triglide), gemfibrozil (Apo-Gemfibrozil, Lopid, Novo-Gemfibrozil).

Interaction Type and Significance
≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**
⊕✗ **Bimodal or Variable Interaction, with Professional Management**
◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**
? **Interaction Possible but Uncertain Occurrence and Unclear Implications**

Probability: **2. Probable**
Evidence Base: ▽ **Mixed**

Effect and Mechanism of Action

Even as it binds other nutrients, such as iron, and tends to produce malabsorption, clofibrate is hypothesized to improve copper nutriture. Leslie M. Klevay, a researcher who has studied copper metabolism extensively, described clofibrate as a "cholesterotropic and cuprotropic" substance. He has observed that clofibrate lowers plasma cholesterol and enhances copper metabolism. Thus, Klevay and others have proposed that clofibrate reduces hypercholesterolemia, at least in part, through its effect on copper deficiency.[15,16] This effect is mediated by an increase in hepatic copper. Possibly as a result of such actions, however, clofibrate has a poor safety profile with significant risk of liver damage, as well as other adverse effects, including increased risk of cancer and pancreatitis. In research involving rats, Fields et al.[17] and others have reported that administration of clofibrate reduces the activity of the lipogenic enzyme glucose-6-phosphate dehydrogenase (G6PD), even though total hepatic lipid was not reduced. Further, clofibrate did not affect hepatic lipid concentration, and the pathology associated with copper deficiency when fructose was fed was not prevented by the consumption of clofibrate. Also, the tendency for hypercholesterolemic people to be more likely to be malnourished in copper than normocholesterolemic people may influence differential responses among various populations and manifest as a change in copper metabolism in response to the drug.

Research

Clofibrate is consistently recognized as altering copper metabolism. However, various researchers have arrived at differing conclusions as to whether the net effect of clofibrate therapy is to enhance or deplete copper status, whether observed changes reflect the drug's action or the metabolic alterations associated with pathology, and the degree to which the interaction is clinically significant.[16,18] Clofibrate may bind copper and reduce absorption, but it also tends to elevate tissue levels, particularly in the liver. In particular, although research consistently indicates that clofibrate is active in animals malnourished in copper, it is still uncertain whether observed changes reflect changes in cholesterol metabolism induced by clofibrate because of a change in copper metabolism or other processes, and how such laboratory findings illuminate clinical practice involving humans.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Copper supplementation may be appropriate. Periodic monitoring is advised.

ESTROGENS, PROGESTINS, AND ESTROGEN-PROGESTIN COMBINATIONS

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCepth 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).

Hormone Replacement Therapy (HRT): Estrogen-Containing and Synthetic Estrogen and Progesterone Analog Medications

HRT, estrogens: Chlorotrianisene (Tace); conjugated equine estrogens (Premarin); conjugated synthetic estrogens (Cenestin); dienestrol (Ortho Dienestrol); esterified estrogens (Estratab, Menest, Neo-Estrone); estradiol, topical/transdermal/ring (Alora Transdermal, Climara Transdermal, Estrace, Estradot, Estring FemPatch, Vivelle-Dot, Vivelle Transdermal); estradiol cypionate (Dep-Gynogen, Depo-Estradiol, Depogen, Dura-Estrin, Estra-D, Estro-Cyp, Estroject-LA, Estronol-LA); estradiol hemihydrate (Estreva, Vagifem); estradiol valerate (Delestrogen, Estra-L 40, Gynogen L.A. 20, Progynova, Valergen 20); estrone (Aquest, Estragyn 5, Estro-A, Estrone '5', Kestrone-5); estropipate (Ogen, Ortho-Est); ethinyl estradiol (Estinyl, Gynodiol, Lynoral).
HRT, estrogen/progestin combinations: Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); conjugated equine estrogens and norgestrel (Prempak-C); estradiol and dydrogesterone (Femoston); estradiol and norethindrone, patch (CombiPatch); estradiol and norethindrone/norethisterone, oral (Activella, Climagest, Climesse, FemHRT, Trisequens); estradiol valerate and cyproterone acetate (Climens); estradiol valerate and norgestrel (Progyluton); estradiol and norgestimate (Ortho-Prefest).
HRT, estrogen/testosterone combinations: Esterified estrogens and methyltestosterone (Estratest, Estratest HS).

Interaction Type and Significance

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

Probability:
3. Possible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Oral contraceptives (OCs) and other exogenous female hormone medications have been shown to elevate intracellular copper and serum copper levels in humans and thereby potentially contribute to alterations in glucose metabolism, oxygen metabolism, and a woman's mental and emotional well-being. Although estrogens are known to affect copper absorption and metabolism, progestins in OCs are believed to be the primary determinant of elevated copper levels.

With regard to hormone replacement therapy (HRT), knowledge continues to evolve as to the respective roles of estrogen, in its various forms, and progestins. The issues and evidence concerning OCs inherently influences and sets the stage for an emerging understanding of interactions between combined HRTs and copper and their clinical implications.

Research

Studies have consistently found OC use positively associated with increased absorption of copper and increased serum copper and ceruloplasmin levels.[19-22] Even though higher

serum copper concentration in women using OCs is well known, uncertainty still surrounds the influence of newer progestin compounds in OCs on serum copper concentration. In a study involving low-estrogen preparations, Liukko et al.[23] noted that copper levels rose significantly in women while using OCs over a 2-year period, but returned to initial levels after the OCs were discontinued. Johnson et al.[24] observed that OCs elevated plasma copper, enzymatic ceruloplasmin, and SOD activity, but not copper absorption and biological half-life, in women age 20 to 39. In a more recent epidemiological study (1998) of 610 nonpregnant and nonlactating women (18-44 years old), Berg et al.[25] reported that although elevated serum copper concentration was found in users of all OC types, elevation was more pronounced among women taking OCs with antiandrogen progestins (56% elevation) than with desogestrel (46%), norethisterone/lynestrenol (42%), or levonorgestrel (34%), after adjusting for multiple covariaters/variables (e.g., age, smoking, alcohol intake).

The effects of hormonal interventions on copper absorption and metabolism occur within a context influenced by gender and life stage. In their study of 44 healthy postmenopausal women, 50 to 60 years old, 18 of whom were treated by oral combined HRT for at least 2 years, and 26 of whom were untreated, Bureau et al.[26] examined plasma trace-mineral levels (Zn, Se, Cr, Mn, Cu), red blood cell antioxidant enzymes (Cu-Zn SOD, Se-GPX, Cu), and urinary excretion (Zn, Cr, Mg, Ca). Plasma copper concentrations were higher in women treated by HRT, whereas erythrocyte copper levels were not modified. Zinc, selenium, and manganese plasma levels; activities of Cu-Zn-SOD; and GSH-PX in erythrocytes were not statistically different between the two groups. The authors interpreted this as suggesting that HRT provides beneficial effects on trace-mineral status related to menopause. In their study of the effects of age and gender on copper absorption, biological half-life, and status, Johnson et al.[24] observed that among younger individuals, 20 to 59 years old, absorption was greater in women (71%) than in men (64%), but that the difference between men and women was negligible among those age 60 to 83. Likewise, biological half-life of ^{67}Cu ranged from 13 to 33 days and differed between men and women age 20 to 59, but not between men and women age 60 to 83. Such findings illuminate the changes in women's metabolism as they age and pass through their reproductive years and into menopause.

Although a causal relationship has not been demonstrated, recent epidemiological studies have shown an increased mortality from cardiovascular diseases in individuals with higher serum copper levels. In 1991, in an epidemiological study of Finnish men, Salonen et al.[27] concluded that high copper status, reflected by elevated serum copper concentration, is an independent risk factor for ischemic heart disease. This issue is of particular interest in the light of recent findings of an increased risk of venous thromboembolism in users of OCs containing newer progestins such as desogestrel, compared with users of other OCs. Further, Reunanen et al.,[28] in a nested case-control study (1996) within a prospective population study, found high serum copper and low serum zinc levels significantly associated with increased mortality from all cardiovascular diseases, particularly coronary heart disease.

Given the recent upheavals in medical consensus and practice guidelines, the emerging research picture, and the as-yet unclear clinical implications of HRT in relation to cardiovascular health and risk, the issues of copper status deserve further attention as part of the continued research.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

At this time, evidence is inadequate to warrant routine monitoring of copper concentrations in female patients using estrogen and progestin medications in the absence of other specific cardiovascular risk factors. OCs can raise serum copper levels, but it is not clear whether or to what degree this occurs at the tissue level. Women using OCs may have increased needs for zinc based on potential depletion, as well as greater needs for folate and vitamins B_{12} and B_6. Individual evaluation of safe and effective hormone dosage levels is necessary. Pending such individualized assessment, patients requesting advice on copper intake might be well advised to refrain from additional supplementation in the absence of therapeutic imperatives involving depletion or deficiency status; zinc coadministration may be appropriate in some cases.

Ethambutol

Evidence: Ethambutol (Myambutol).
Extrapolated, based on similar properties: Isoniazid (isonicotinic acid hydrazide, INH; Laniazid, Nydrazid); combination drugs: isoniazid and rifampicin (Rifamate, Rimactane); isoniazid, pyrazinamide, and rifampicin (Rifater).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
◇≈≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
2. Probable

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

The antimycobacterial agent ethambutol (EMB) forms chelate complexes with the bivalent metal ions (copper and zinc) participating in RNA biosynthesis or stabilization. Clinical research and case reports have consistently found that the optic neuropathy associated with ethambutol results from its effect on copper metabolism. Both ethambutol and its fellow antituberculosis agent isoniazid have been implicated as causes of reduced visual acuity, visual field defects, and disturbances of color vision.

Research

Findings from animal studies indicate that ethambutol alters trace-mineral metabolism through its chelating action. Binding of copper(II) and zinc(II) by 2,2′-(ethylenediimino)-dibutyric acid (EDBA), the metabolic oxidation product of dextro-2,2′-(ethylenediimino)-di-1-butanol (ethambutol), may account for many of the adverse effects of EMB treatment. In particular, ethambutol produced significant decreases in heart copper, kidney zinc, plasma zinc, and liver copper and zinc, not attributable to changes in dietary intake.[9,29]

The principal adverse effect of ethambutol is an optic neuropathy with clinical features closely paralleling a mitochondrial hereditary optic neuropathy (Leber's). As noted, EMB and isoniazid have been implicated in reduced visual acuity, visual field defects, and color vision disturbances. Research consistently indicates that chelation of copper causes EMB-induced optic neuropathy by precluding normal cytochrome-c oxidase activity and mitochondrial metabolism in the optic nerve. An in vitro study by Kozak et al.[30] (1998) suggests that if copper were given to patients to prevent EMB-induced optic

neuropathy, such supportive supplementation would not compromise EMB's bacteriostatic properties against *Mycobacterium tuberculosis* and *Mycobacterium avium*. In concluding their study of 42 Congolese patients with tuberculosis receiving ethambutol treatment, Kaimbo et al.[31] emphasized the importance of color vision examinations in the detection of the complications of EMB treatment.

Nutritional Therapeutics, Clinical Concerns and Adaptations

Coadministration of copper with ethambutol may reduce adverse effects, particularly on the optic nerve and related functions, typically associated with EMB use. Monitoring of visual function is generally appropriate during ethambutol therapy. Supervision is advisable but may not be necessary because no known adverse effects are associated with concomitant copper intake. However, given the consistent evidence of EMB's copper-binding properties, individuals taking concomitant copper are advised to allow at least a 2-hour interval after taking ethambutol to avoid diminished therapeutic effect from the nutrient. The therapeutically appropriate level of copper would be 1 to 2 mg per day.

Famotidine and Related Histamine (H_2) Receptor Antagonists

Evidence: Famotidine (Pepcid, Pepcid AC, Pepcid RPD).
Extrapolated, based on similar properties: Cimetidine (Tagamet, Tagamet HB), nizatidine (Axid, Axid AR), ranitidine (Zantac); combination drug: ranitidine, bismuth, and citrate (Tritec).
See also Antacids and Cimetidine.

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **3. Possible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

The normally acidic environment of the stomach facilitates optimal absorption of copper and other nutrients. Famotidine may induce a copper deficiency by inhibiting copper absorption and precipitating dietary copper.

Research

Famotidine may reduce absorption of copper by interfering with normal gastrointestinal (GI) physiology and function.[5,32]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Repeated use of famotidine, or other H_2 receptor antagonists (H_2RAs), over an extended period may tend to promote a deficiency of affected nutrients, such as copper. Nevertheless, evidence is lacking to support the conclusion that clinically significant adverse effects of copper deficiency due to famotidine are common. Nevertheless, individuals who regularly use famotidine, or another H_2RA medication, for an extended time may benefit from 1 to 2 mg of copper daily, possibly in the form of a multivitamin/mineral formula, taken at least 2 hours away from the drug.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

COX-1 inhibitors: Diclofenac (Cataflam, Voltaren); combination drug: diclofenac and misoprostol (Arthrotec); diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), furbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen); combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen); indomethacin (indometacin; Indocin, Indocin-SR), ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Saltflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).
COX-2 inhibitor: Celecoxib (Celebrex).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **3. Possible**

Evidence Base: ▽ **Mixed**

Effect and Mechanism of Action

Copper complexes of NSAIDs are more effective in their anti-inflammatory effect and less toxic than the parent NSAID substances. Based on these observations, Sorenson[33] proposed that copper complexes of NSAIDs are their active metabolites. However, continuing research by Berthon, Brumas, Miche, and associates indicates that the extra anti-inflammatory activity induced by copper on NSAIDs appears to be independent of any Cu(II)-NSAID association in vivo. On the contrary, the binding of inactive substances with copper(II) at inflammatory sites seems to be essential to their activation by copper. Parallel investigations suggest that the apparent copper potentiation of NSAIDS may be caused by copper interactions with endogenous histidine.[34-36]

Research

Kishore[37] reported that administration of copper aspirinate to arthritic rats for 20 days increased hepatic copper concentrations. Such animal models of inflammation have also shown that the copper chelate of aspirin is active at one-eighth the effective amount of aspirin. These copper complexes are less toxic than the parent compounds as well. Based on such findings, speculation has been raised that copper supplementation might enhance the anti-inflammatory effects of NSAIDs while reducing their ulcerogenic effects. However, the ability of NSAIDs to influence copper metabolism is still poorly understood, and apart from the proposed SOD-like activity of copper salts in vivo, knowledge is limited as to how copper-NSAID interactions participate in the regulation of the inflammatory process. Interactions between copper and anti-inflammatory medications deserve continued research, especially within the context of deepening our understanding of copper absorption and metabolism and the inflammatory responses of the immune system.

Clinical Implications and Adaptations

Copper complexes may be more active than parent NSAIDs, but concomitant copper will not necessarily result in or amplify such effects. Coadministration of 1 to 2 mg/day of copper might enhance the anti-inflammatory activity of NSAIDs while reducing potential adverse effects caused by such medications. However, such action is not based on a clear, consistent, and substantive pattern of evidence; some research questions such a conclusion. Nevertheless, the risk of adverse effects from low levels of copper intake would be

negligible and probably less than the potential risk of adverse effects typically associated with use of NSAIDs.

Penicillamine and Related Chelating Agents

Deferasirox (Exjade), desferoxamine (desferrioxamine mesilate, desferoxamine mesylate; Desferal), EDTA (ethylenediaminetetraacetic acid), penicillamine (Cuprimine, Depen), tetrathiomolybdate (TM), trientine (trien, trienthylene tetramine; Syprine).

Interaction Type and Significance

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

≈◇◇ **Drug-Induced Nutrient Depletion, Supplementation Contraindicated, Professional Management Appropriate**

Probability:
1. Certain

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Penicillamine, trientine (trienthylene tetramine), and tetrathiomolybdate are chelating agents that bind metals and carry them out of the body. Tetrathiomolybdate was initially developed as a less toxic copper chelator than penicillamine and is now considered the treatment of choice for Wilson's disease, with zinc acetate maintenance after the copper levels are sufficiently low. Oral administration of copper, as well as aluminum, iron, and magnesium salts, and possibly other minerals (e.g., calcium, zinc), may decrease the GI absorption and bioavailability of these chelating agents, and vice versa. The medication's chelation of polyvalent metal ions resulting in a nonabsorbable complex constitutes the operative mechanism.

Research

Penicillamine is used to treat people with Wilson's disease, cystinuria, and severe rheumatoid arthritis. Wilson's disease (WD) is an autosomal recessive disease that causes excessive copper deposition in the liver, basal ganglia, kidney, cornea, and other tissues, with resultant hepatic, neurological, and visual sequelae. Medical research continues to clarify the pathophysiology of WD, with major advances in recent years. The key strategy of current conventional medical treatment focuses on reducing the amount of copper in the liver and other tissues by administering both copper-chelating agents and a low-copper diet. Although major progress has been achieved in the treatment of WD, significant controversy remains as to the optimal treatment of individuals in the various stages of the disease. Specifically, the relative roles of penicillamine, trientene, and tetrathiomolybdate in the initial treatment of the symptomatic patient with WD continue to be researched, debated, and emergent.[9,38,39] Copper control using these agents has also emerged as an antiangiogenic anticancer therapy.[40,41]

Penicillamine prevents the formation or promotes the solubilization of copper-rich particles occurring in lysosomes of hepatocytes and Kupffer cells in the livers of individuals with WD. Once chelated with D-penicillamine, copper can then be excreted into urine. However, research indicates that the mobilization of copper by D-penicillamine is limited because of the binding of the metal to metallothioncin in liver cytosol. This form of copper, even at relatively high concentrations, appears to be well tolerated.[42,43]

Penicillamine use is associated with numerous adverse effects, often severe, such as systemic lupus erythematosus (SLE) and nephrotic syndrome, which occur in 20% to 25% of all patients. In cases where D-penicillamine has to be withdrawn, trientine becomes the drug of choice and is generally considered to be as effective as penicillamine. Trientine is sometimes administered as a first-choice drug to individuals with neurological symptoms.[42-44]

Again, among the primary therapeutic uses of chelating agents such as penicillamine and trientine is the treatment of WD, in which toxic deposits of copper accumulate. Penicillamine is also used to treat individuals with cystinuria and severe rheumatoid arthritis.[33,38,45]

Copper also plays an essential role in promoting angiogenesis. Tumors that become angiogenic acquire the ability to enter a phase of rapid growth and exhibit increased metastatic potential, the major cause of morbidity and mortality in cancer patients. Human and animal research on breast, lung, and other cancers indicates that copper deficiency induced by chelating agents, such as tetrathiomolybdate, significantly impairs tumor growth and angiogenesis through suppression of nuclear factor kappa B (NF-κB), contributing to a global inhibition of NF-κB–mediated transcription of proangiogenic factors.[46,47] NF-κB expression is also associated with the development of both chemotherapy and radiation resistance in cancer cells.

Note: Given the high risk of teratogenicity, based on animal studies, and the known adverse effects associated with many chelating agents, Brewer et al.[48] and other researchers have investigated the treatment of WD using tetrathiomolybdate, followed by zinc monotherapy or complementary use of zinc salts, using zinc in particular during pregnancy and with children.

Clinical Implications and Adaptations

Given the therapeutic objective of reducing toxic levels of copper in the body by increasing urinary excretion of the mineral, individuals with WD should minimize dietary intake of copper and avoid consuming copper supplements of any kind, even in the small doses found in most multivitamin/mineral formulas. In individuals taking any of these chelating agents to reduce copper levels, the consumption of any supplemental copper would obviously have an adverse effect on the drug's performance.

If copper (or iron) supplementation is incidental to the consumption of other medications or supplements or therapeutically indicated in some extraordinary circumstance, substances containing such minerals should be taken 2 hours before or after penicillamine, trientine, or tetrathiomolybdate to minimize interference with the medication's effects.

Note: Clinicians should also be aware of chlorophyllin, a water-soluble copper complex of chlorophyll that is becoming increasingly popular as a nutritional supplement. Chlorophyllin has antimutagenic and anticarcinogenic properties, but it is also a source of copper and needs to be considered as part of the standard supplement inventory inquiry.

Valproic Acid and Related Anticonvulsant Medications (AEDs)

Evidence: Divalproex semisodium, divalproex sodium (Depakote), sodium valproate (Depacon), valproate semisodium, valproic acid (Depakene, Depakene Syrup).
Similar properties but evidence lacking for extrapolation: Carbamazepine (Carbatrol, Tegretol), clonazepam (Klonopin), clorazepate (Tranxene), ethosuximide (Zarontin), ethotoin

(Peganone), felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), levetiracetam (Keppra), mephenytoin, mephobarbital (Mebaral), methsuximide (Celontin), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), phenobarbital (phenobarbitone; Luminal, Solfoton), phenytoin (diphenylhydantoin; Dilantin, Phenytek), piracetam (Nootropyl), primidone (Mysoline), topiramate (Topamax), trimethadione (Tridione), vigabatrin (Sabril), zonisamide (Zonegran).

Interaction Type and Significance

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

Probability: **4. Plausible**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Valproic acid (VPA) may induce increased excretion of copper into the bile, thereby disrupting the homeostatic balance of copper and causing abnormalities in serum copper concentration.

Research

In several studies of children with epilepsy being treated with VPA, serum copper levels remained unchanged relative to control groups.[49–53] Subsequently, however, Kaji et al.[54] investigated serum zinc and copper levels in epileptic children treated with VPA and/or other antiepileptic drugs (AEDs). They found that patients "treated with VPA monotherapy had significantly lower levels of serum Cu" than normal controls, as did those "treated with VPA in addition to some other AED," whereas those "treated with AEDs except for VPA" exhibited serum copper concentrations "not statistically different from those of control subjects." These researchers suggested that physicians should watch for potential symptoms of copper deficiency, even though none of their patients showed any symptoms of copper deficiency at the time of the study.[54] Suzuki et al.[55] reported that long-term anticonvulsant therapy could induce alterations in both the metabolism and the distribution of copper, zinc, and magnesium, and that gender was a significant factor in the resultant effects.

Clinical Implications and Adaptations

No definitive evidence has emerged as to the prevalence or clinical significance of copper depletion or deficiency resulting from valproic acid. Physicians prescribing VPA, especially in children, should consider coadministration of copper to restore proper trace-mineral balance and avoid possible deficiency. Inadequate consumption of copper through dietary sources is common. Copper (and zinc) status should be monitored, particularly in epileptic children taking valproate derivatives. Coadministration of copper at 1 to 3 mg daily may be beneficial, especially for individuals taking zinc supplements.

Zidovudine (AZT) and Related Reverse-Transcriptase Inhibitor (Nucleoside) Antiretroviral Agents

Evidence: Zidovudine (azidothymidine, AZT, ZDV, zidothymidine; Retrovir).

Extrapolated, based on similar properties: Abacavir (Ziagen), didanosine (ddI, dideoxyinosine; Videx), dideoxycytidine (ddC, zalcitabine; Hivid), lamivudine (3TC, Epivir), stavudine (D4T, Zerit), tenofovir (Viread); zidovudine combination drugs: zidovudine and lamivudine (Combivir); abacavir, lamivudine, and zidovudine (Trizivir).

Protease inhibitors: Amprenavir (Agenerase), atazanavir (Reyataz), brecanavir, darunavir (Prezista), fosamprenavir (Lexiva), indinavir (Crixivan), nelfinavir (Viracept), ritonavir (Norvir), saquinavir (Fortovase, Invirase), tipranavir (Aptivus); combination drugs: lopinavir and ritonavir (Aluvia, Kaletra); saquinavir and ritonavir (SQV/RTV).

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Nutrient Adverse Effect**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **3. Possible**

Evidence Base: ▽ **Mixed**

Effect and Mechanism of Action

Coadministration of zinc during AZT therapy will tend to deplete copper during extended therapy. The antagonistic relationship between copper and zinc might be a concern, given the importance of zinc for immune status.

Research

Preliminary human research by Baum et al.[56] published in 1991 suggested AZT therapy might cause decreased levels of zinc and copper along with a significant increase in red cell folate. The level of plasma zinc appeared to be particularly important in maintaining immune function in the zidovudine-treated group. Also in 1991, Graham et al.[57] reported that higher serum copper and lower serum zinc levels predicted progression to acquired immunodeficiency syndrome (AIDS) independently of baseline CD4+ lymphocyte level, age, and calorie-adjusted dietary intakes of both nutrients. Allavena et al.[58] observed alterations in parameters of several trace minerals during AZT treatment but reported that copper values were within normal limits. More recently, however, in a 2001 paper on survival in a cohort of HIV-1–infected homosexual men, Lai et al.[59] reported that although plasma zinc inadequacy or the plasma copper/zinc ratio may be useful predictors of survival in human immunodeficiency virus type 1 (HIV-1) infection, plasma levels of copper were not significantly associated with mortality. In a study involving 86 subjects with known HIV infection, Jimenez-Exposito et al.[60] found that AIDS patients with active opportunistic infection showed significantly lower serum concentrations of vitamin A and significantly higher serum concentrations of copper. They concluded that these findings were correlated with various inflammatory parameters more than with nutritional status.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The clinical significance of these findings remains unclear with regard to dietary intake of copper and potential therapeutic effects of an interaction between copper and zidovudine. Copper appears to play an important role in the immune system's inflammatory response, but no conclusive evidence has emerged indicating that copper coadministration would be

therapeutically beneficial. However, any extended supplementation of zinc might induce a copper deficiency and would suggest a need for countervailing copper, 1 to 2 mg/day. Ultimately, the evidence at this point indicates the importance of monitoring nutritional status of individuals with HIV infection, whether or not they are undergoing retroviral therapy such as with zidovudine.

NUTRIENT-NUTRIENT INTERACTIONS

Iron

The metabolic pathways and functions of copper and iron are intertwined, and the minerals have many similarities and some significant interactions. Copper stimulates intestinal absorption and improves utilization of iron, whereas iron can inhibit copper absorption. Both are transition elements that can participate in redox reactions; both can also be sequestered by proteins and thus prevent undesirable redox reactions. Iron deficiency can contribute to increased concentrations of copper in tissues, and copper deposition can be a significant risk in some anticancer therapies aimed at altering iron status.

Molybdenum

Within integrative chemotherapy regimens, as well as the treatment of Wilson's disease, administration of tetrathiomolybdate, which contains molybdenum at the center of four chelating sulfhydryl groups, can serve as an effective copper-chelating agent with significantly fewer adverse effects than most conventional copper chelators.

Vitamin C

Vitamin C intake at pharmacological doses for extended periods can lead to a depletion of copper, in the absence of compensatory copper intake supplementation.

Zinc

Zinc significantly interferes with copper absorption.[61] Zinc induces intestinal cell metallothionein, which binds copper and prevents its transfer into blood. eventually the intestinal cells die and slough, taking the trapped copper with them in the stool, thus preventing intestinal absorption of copper. Prolonged intake of supplemental zinc, particularly longer than 1 month, warrants compensatory copper, except for individuals with Wilson's disease and those whose therapeutic strategy employs zinc as an anticopper agent. Copper supplements should be taken at least 2 hours after zinc supplements.

The 61 citations for this monograph, as well as additional reference literature, are located under Copper on the CD at the back of the book.

Iron

Nutrient Name: Iron.
Synonyms: Iron salts; fer; ferric sulfate; ferrous carbonate anhydrous, ferrous citrate, ferrous fumarate, ferrous gluconate, ferrous glutamate, ferrous glycinate, ferrous glycine sulphate, ferrous lactate, ferrous picolinate, ferrous pyrophosphate, ferrous succinate, ferrous sulfate; carbonyl iron; iron-polysaccharide, iron dextran, iron-ovotransferin, iron sorbitol, iron sucrose, sodium ferric gluconate.
Elemental Symbol: Fe.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Acetylsalicylic acid (ASA, aspirin) ☼/≈≈	Aspirin causes gastrointestinal (GI) irritation and bleeding, which may be slight but acts cumulatively with chronic use to increase risk of iron deficiency and anemia. Iron supplementation can reverse adverse hematological effects of ASA therapy.	Short-term iron may be appropriate if deficiency or depletion present; separate intake, monitor. Address dietary and lifestyle factors contributing to inflammation and pain.
Angiotensin-converting enzyme (ACE) inhibitors ◈◈/☼/⊕✗/✗✗	Coadministration of iron can abolish cough induced by ACE inhibitors, possibly by inhibiting NO synthase activity in bronchial epithelial cells. However, iron and ACE medications may bind and reduce absorption of both agents. IV iron may be appropriate in certain anemic hemodialysis patients treated with an ACE inhibitor but this treatment is controversial, complicated, and risky.	Coadminister, when indicated. Separate intake by 3 or more hours. IV iron requires active supervision by experienced provider(s), with broad antioxidant support.
Antacids and gastric acid–suppressive medications Histamine (H_2) receptor antagonists Proton pump inhibitors (PPIs) ☼/≈≈/◈◈	Inhibition of gastric acid environment can inhibit reduction of ferric iron and reduce absorption and bioavailability of dietary iron. History of GI bleeding and increased risk of iron depletion common in patient population. Some agents may bind with iron and impair absorption of either or both substances. Adverse effects on iron status may be slow to develop and difficult to assess.	Short-term iron may be appropriate if deficiency or depletion present; separate intake, monitor. Address dietary and lifestyle factors contributing to dyspepsia, GERD, and ulcers.
Bile acid sequestrants ◈◈/≈≈≈≈/◈	Simultaneous intake of iron and bile sequestrants may result in binding and reduced absorption due to formation of poorly absorbed chelate complexes. Drug action may be impaired with interaction. Evidence is limited and inconsistent regarding probability and significance of iron depletion.	Low risk of significant interaction if oral intake separated by at least 2 hours.
Bisphosphonates ◈◈/≈≈	Binding may occur with simultaneous intake and inhibit absorption and bioavailability of both agents. Decreased therapeutic activity probable with interaction; minimal effect with separation of intake. Limited evidence on long-term effects.	If iron is indicated, separate intake by 2 or more hours to avoid interference. Monitor iron status.
Carbidopa, levodopa Antiparkinsonian medications ◈◈/≈≈	Simultaneous intake of carbidopa or levodopa and iron (especially ferric) may result in binding and reduced absorption due to formation of poorly absorbed chelate complexes. Medication may also cause autoxidation to ferric form.	Iron may be contraindicated in this patient population. If indicated, separate intake by at least 2 hours and monitor iron status.
Cefdinir Cephalosporin antibiotics ◈◈	Chelation between cephalosporin antibiotics and iron likely to impair absorption and bioavailability of both agents if ingested concurrently. Decreased therapeutic activity with interaction; minimal effect with separation of intake. Iron depletion plausible with extended use, but not established or probable. Caution warranted regarding supplementation during infection.	Discontinue iron or separate intake during short-term therapy. Mineral supplementation may be appropriate with extended therapy but caution warranted; separate intake by several hours.
Chloramphenicol ☼/◈≈≈/◈	Chloramphenicol can inhibit erythropoiesis and red cell maturation, thus delaying or impeding iron therapy; it can also cause aplastic anemia. Dosage levels < 25-30 mg/kg are usually effective without adversely affecting bone marrow.	Discontinuation of chloramphenicol may be necessary if treating patients with anemia. Largely replaced by alternatives as a standard treatment in recent years.
Chlorhexidine ✗✗	Concurrent intake of chlorhexidine and iron may stain teeth.	If iron is indicated, separate intake by at least 2 hours to avoid interaction.
Clofibrate ◈◈/≈≈/◈	Chelation between clofibrate and iron likely to impair absorption and bioavailability of both agents if ingested concurrently.	If iron is indicated, separate intake by 3 hours to avoid interference. Monitor iron status.
Desferoxamine ☼/◈◈/✗✗	Desferoxamine is a chelating agent applied to treat overload and intoxification involving iron and other metals. It binds to iron and increases iron excretion. Intake of iron (supplemental or as iron-rich foods) is contraindicated, as contrary to the therapeutic intent.	Discontinue supplemental iron and decrease dietary intake immediately. Close supervision and monitoring necessary. Supplementation with other nutrients may be appropriate; separate intake by several hours.
Dimercaprol ✗✗✗	Dimercaprol is used as an antidote in arsenic, cadmium, lead, and mercury poisoning in inpatient settings. Iron intake during dimercaprol therapy may cause kidney damage but is often appropriate after such treatment.	Avoid supplemental iron during dimercaprol therapy. Close supervision and monitoring necessary. Supplementation with iron may be appropriate 24 hours or more following conclusion of dimercaprol.
EDTA ☼/◈◈/✗✗	EDTA is a chelating agent applied to treat overload and intoxification involving iron and other metals. It binds to iron and increases iron excretion. Intake of iron (supplemental or as	Avoid supplemental iron and decrease dietary intake. Close supervision and monitoring contrary necessary. Supplementation with

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
	iron-rich foods) is contraindicated, as opposed to the therapeutic intent. Some iron chelates containing EDTA are used for iron fortification.	iron and other nutrients may be appropriate with extended therapy; separate intake by several hours.
Erythropoiesis-stimulating agents ⊕⊕/⊕✗/✗✗/✗✗✗	Synergistic interaction often used in treatment of oncology patients with functional iron deficiency or anemia but remains controversial. Coadministration may enhance epo-induced erythropoiesis, but risk of adverse effects is significant if applied prematurely, with inadequate iron stores, during anemias of chronic inflammation, or in unstable oncology patients. Further research warranted. Iron administration in hemodialysis patients is often contraindicated, although oral heme iron may be effective.	Assess endogenous EPO level. Coadminister iron with iron deficiency if no response to initial EPO therapy, under close supervision and monitoring of iron status, especially stores. Oral forms may be safer than IV administration.
Fluoroquinolone/quinolone antibiotics ✗✗/◇◇/≈≈	Chelation between this class of antibiotics and iron likely to impair absorption and bioavailability of both agents; similarly with other minerals. Decreased therapeutic activity with interaction; minimal effect with separation of intake. Iron deficiency and effects of iron depletion plausible with extended use, but not established or probable. Iron-ovotransferrin combines directly with gut transferrin receptors and minimizes risk of binding to drug. Caution warranted regarding supplementation during infection.	Avoid iron or separate intake during short-term therapy. Iron-ovotransferrin may be most effective form. Mineral supplementation may be appropriate with extended therapy, but caution warranted regarding iron, even with established depletion; separate intake by several hours.
Hyoscyamine ≈≈/☼/◇	Hyoscyamine can impair iron absorption, but mechanism, occurrence, and clinical significance not fully elucidated. Potential for decreased therapeutic activity with simultaneous intake. Iron depletion and effects of iron depletion plausible with extended, use but not established or probable.	Iron supplementation with iron or other appropriate minerals may be appropriate with extended therapy; separate intake by several hours.
Indomethacin Nonsteroidal anti-inflammatory drugs (NSAIDs) ≈≈/◇◇/☼/⊕✗/✗	NSAIDs, especially indomethacin, can cause GI irritation and bleeding, which may be slight but acts cumulatively with chronic use to increase risk of iron deficiency and anemia. Iron supplementation can reverse adverse hematological effects of NSAID therapy.	Short-term iron may be appropriate if deficiency or depletion present; separate intake, monitor. Address dietary and lifestyle factors contributing to inflammation and pain.
Interferon alpha ✗✗✗	Iron excess can contribute to inflammatory processes, support infectious agents, and reduce response to interferon. Iron reduction can enhance positive outcomes in interferon therapy. Phlebotomy may enhance interferon therapy outcomes, as may low-iron diet.	Avoid supplemental iron and recommend low-iron, vegetarian diet. Close supervision and monitoring necessary. Phlebotomy may be appropriate.
Levothyroxine Thyroid hormones ✗✗/◇◇/≈≈/⊕⊕	Thyroid therapy may be enhanced with iron coadministration. However, simultaneously ingested thyroxine and iron likely to bind to form poorly soluble chelate complex and thereby impair absorption and bioavailability of both agents. Decreased therapeutic activity with interaction; minimal effect with separate intake. Consensus regarding probability of binding, but evidence lacking for iron depletion, plausible with extended use.	Comorbid conditions may require both agents. Separate intake by several hours to avoid binding and interference. Monitor TSH; may need to adjust dosage levels.
Methyldopa ✗✗/◇◇/≈≈	Simultaneously ingested methyldopa and iron likely to bind to form poorly soluble chelate complex and thereby impair absorption and bioavailability of both agents. Decreased antihypertensive activity probable with interaction. Decreased interference with separation of intake. However, medication may also cause autoxidation to the ferric form. Iron depletion and effects of iron depletion plausible with extended use, but not established or probable.	If iron is indicated, separate intake by at least 2 hours to avoid interference.
Neomycin ≈◇◇/⊕✗/⊕	Neomycin known to impair absorption of iron and many other nutrients; concurrent intake may alter drug activity. Clinical significance may vary depending on individual's iron status. Iron deficiency and effects of nutrient depletion probable with extended use; adverse effect improbable with short-term or topical use. Caution warranted regarding supplementation during infection.	Iron supplementation with iron or other appropriate nutrients may be appropriate with extended therapy, but caution warranted regarding iron, even with established depletion; separate intake by several hours.
Oral contraceptives (OCs) ⊕⊕/◇◇	OCs may support iron status and reduce need for supplementation by reducing menstrual blood loss. Serum ferritin, serum transferrin, serum iron, TIBC, MCH, and MCHC levels may be greater, but RBC and hematocrit levels often lower in OC users. Systemic implications of exogenous hormones, in diverse formulations and with chronic administration, on multiple levels of iron metabolism and storage not fully elucidated. Continued research into responses among variable individuals to these complex medications is warranted.	Women using OCs may have reduced need for iron supplementation, although possibly higher needs for folate and vitamins B_{12} and B_6. Individual evaluation of safe and effective hormone dosage levels necessary. Periodic assessment of serum ferritin, ferritin saturation, and/or serum transferrin receptor levels may be warranted.
Penicillamine ✗✗/◇◇/⊕✗/ ≈≈	Penicillamine is a chelating agent applied to treat overload and intoxification involving copper, iron, and other metals. It binds to iron and increases iron excretion. Intake of iron (supplemental or as iron-rich foods) can bind medication doses when ingested concurrently. However, abrupt discontinuation of ongoing iron intake may lead to rapid elevation in circulating penicillamine levels and resultant nephrotoxicity. Iron intake may also be contraindicated, as opposed to the therapeutic intent, i.e., copper chelation.	Avoid concurrent iron and dietary intake; tapered reduction needed in discontinuing supplemental iron. Close supervision and monitoring necessary. Supplementation with iron and other nutrients may be appropriate with extended therapy if depletion detected; separate intake by several hours.
Sulfasalazine ◇◇/≈≈/◇	When ingested concurrently, iron can bind to sulfasalazine, interfering with its breakdown into 5-aminosalicylic acid (5ASA) and sulfapyridine. This pharmacokinetic interaction can reduce absorption, bioavailability, and therapeutic activity of the prodrug, its constituents, and the nutrient, but can be minimized by separation of intake. Iron	Separate intake by several hours to avoid binding and interference. Iron supplementation may be warranted if bleeding, anemia, and/or iron depletion established,

Continued

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
	depletion possible with extended use, particularly in patient population with ulceration and GI bleeding, but not established.	but caution is appropriate to avoid aggravating inflammation.
Tetracycline antibiotics ◇◇/≈≈/◇	Chelation between iron and tetracycline-class antibiotics and impaired absorption of both to clinically significant degree probable with concurrent intake. Iron intake, even small amounts, can significantly impair antimicrobial activity. General consensus despite minimal direct evidence. Iron depletion with extended tetracycline use but evidence lacking. Caution warranted regarding supplementation during infection.	Discontinue iron (including iron-rich foods) or separate intake during short-term therapy. Iron supplementation may be appropriate with extended therapy, but caution warranted, even with established depletion; separate intake by several hours.
Trientine XX/◇◇/⊕X/≈≈	Trientine is a chelating agent applied to treat copper overload and toxicity, particularly in Wilson's disease. Simultaneous ingestion with iron likely to bind to form poorly soluble chelate complex and thereby impair absorption and bioavailability of both agents. Anemia is common adverse effect of trientine due to increased iron excretion, as well as decreased iron absorption, with children, menstruating women, and pregnant women at greatest risk.	Separate intake by several hours to avoid binding and interference. Iron supplementation may be warranted if anemia and/or iron depletion established; separate intake by several hours.

NO, Nitric oxide; *IV*, intravenous; *GERD*, gastroesophageal reflux disease; *EPO*, erthyropoietin; *TSH*, thyroid-stimulating hormone; *TIBC*, total iron-binding capacity; *MCH*, mean corpuscular hemoglobin; *MCHC*, MCH concentration; *RBC*, red blood cell.

NUTRIENT DESCRIPTION

Chemistry and Forms

Oxidation states: Ferric (Fe^{3+}) iron, ferrous (Fe^{2+}) iron.
Heme and nonheme.

Physiology and Function

Iron is an essential mineral that plays a vital role in numerous essential biochemical pathways. The principal functions of iron involve DNA synthesis and cell formation, oxygen sensing and cellular uptake, oxygen transport and storage within blood and muscle, electron transfer and the conversion of glucose to adenosine triphosphate (ATP), both antioxidant and beneficial pro-oxidant functions, and regulation of intracellular iron. Within the human body, iron occurs primarily in functional forms, such as proteins, particularly hemoglobin and myoglobin, and in transport and storage forms, such as transferrin, ferritin, and hemosiderin. Iron is also a constituent of numerous enzymes, amino acids, hormones, and neurotransmitters. Iron is a key component of enzymes responsible for oxidative phosphorylation and ATP generation in the mitochondria and for synthesis of serotonin and dopamine. Iron is essential for the synthesis of carnitine, a critical compound in fatty acid metabolism, and for the operation of the cytochrome P450 system and other cytochromes. It also acts as a cofactor in the synthesis of collagen and elastin.

Iron absorption is highly dependent on maintenance of the normal biochemical environment and coordination of upper gastrointestinal (GI) function. Iron must be in ferrous form to be absorbed. When iron is found in meat, it is in the *heme* form. When the source of iron is from plants or from animal products such as milk, eggs, and cheese, it is referred to as *nonheme* iron. In the heme form, once it is cleaved from the food, iron may be converted to hemin (Fe^{3+}), which can be directly absorbed intact by the mucosal cell into the blood. Absorption of heme iron is about 10 times that of nonheme iron, depending on whether body stores are replete. In the nonheme form, iron must be cleaved from its food source, then reduced from the ferric to the ferrous form, facilitated by gastric hydrochloric acid, before it can be absorbed. Likewise, ascorbic acid, found in foods and supplements, increases absorption by keeping the ferrous form from oxidizing to ferric in the gastric environment. Iron absorption is a slow process, taking between 2 and 4 hours, and occurring principally in the duodenum and proximal jejunum. Iron is absorbed from the small intestine in different forms at 5% to 15% of intake. Absorption percentages, as opposed to excretion, are largely responsible for regulation of body iron content and respond to levels of body iron stores. Thus, low body iron levels lead to improved absorption.

Iron is oxidized back to ferric state for transport and then transported within the mucosal cell and in the blood bound to the protein transferrin. Transferrin is usually saturated to about one-third its total iron-binding capacity (TIBC). If no iron is needed, transferrin remains saturated and less is absorbed from the intestinal mucosal cells. The transferrin that remains in the cells eventually is sloughed away with the mucosal cells at the end of their 2- to 3-day life cycle. If iron is needed, the transferrin is less saturated when it reaches the intestinal mucosal cells, and more iron passes from the mucosal cell to the transferrin. Thus, the degree of saturation of transferrin is also used as a measurement of body stores of iron. Iron is stored in the liver, spleen, and bone marrow as ferritin and hemosiderin. The normal human body contains 3 to 4 grams of iron (40-50 mg/kg body weight), 75% of which (~36 mg/kg) is present in metabolically active compounds. A storage pool maintains the remaining 25% (~10 mg/kg in men and ~5 mg/kg in menstruating women) in a form that is readily available for use if metabolically active iron is depleted for any reason.

The body's capacity to eliminate iron is limited and, once absorbed, largely occurs through blood loss. Under normal conditions, the largest loss of iron is through bleeding in menstruating women; although considerably greater than other channels, these iron losses vary widely from individual to individual. Very small amounts of iron are also excreted through sweat and normal exfoliation of hair, skin, and nails. Most iron expelled in the feces is nonabsorbed iron from dietary intake.

Hemoglobin and myoglobin are proteins involved in the transport and storage of oxygen that contain heme, an iron-based compound. *Hemoglobin* is the primary protein responsible for oxygen transport in red blood cells (RBCs) and constitutes approximately two thirds of the iron in the human body. Hemoglobin functions to acquire oxygen efficiently and rapidly during its short contact in oxygenated lung tissue,

transporting that oxygen from the lungs throughout the circulatory system and releasing it as needed into the target tissues. *Myoglobin* is the primary protein responsible for oxygen transport and regulation of short-term oxygen storage within myocytes and for the coordination of oxygen influx with the physiological demands of muscle function. Iron's ability to shift between its ferrous or reduced state (Fe^{2+}) and its oxidized ferric state (Fe^{3+}) enables it to hold or release oxygen and empowers its functional activity in electron transport and energy production.

Iron plays a critical role in the body's ability to sense oxygen and dynamically respond to variable conditions. Prolyl hydroxylase is an iron-dependent enzyme that participates in regulating the body's response to hypoxic conditions, such as high altitude or impaired function caused by lung disease. In particular, hypoxia inducible factors (HIFs) are transcription factors that respond to decreases in cellular oxygen tension characteristic of hypoxic conditions, by binding to genetic response elements that encode various proteins involved in compensatory responses to hypoxia, and increase their synthesis. Thus, in response to cellular oxygen tension, prolyl hydroxylase will either rapidly degrade HIF-alpha subunits or bind them to HIF-beta subunits to create an active transcription factor capable of entering the nucleus and binding to specific response elements on genes.

Iron, in both heme and nonheme forms, is part of several enzymes involved in electron transport, cellular energy production, and cellular detoxification. Cytochromes are heme-containing compounds critical to mitochondrial electron transport in the synthesis of ATP. In the liver the cytochrome P450 family of enzymes, in particular, metabolizes a wide range of biological molecules and exogenous toxins, including detoxification and metabolism of pharmaceuticals. NADH dehydrogenase and succinate dehydrogenase are among several enzymes containing nonheme iron involved in energy metabolism. Iron is also prominent in the synthesis of carnitine, an amino acid that plays an essential role in the metabolism of fatty acids. Thus, in a state of iron deficiency, an individual will fatigue more readily because of inadequate accessible oxygen and impaired synthesis of ATP.

Iron is well known for its tendency to cause oxidative damage, but it is also part of the antioxidant enzymes *catalase* and *peroxidase*, which serve to quench potentially damaging reactive oxygen species (ROS). These heme-containing enzymes catalyze the conversion of hydrogen peroxide to water and oxygen and thus prevent its buildup within cells. *Myeloperoxidase*, another heme-containing enzyme, catalyzes neutrophils to synthesize hypochlorous acid, an ROS, to be used within the immune system's response to pathogenic bacteria.

Iron is intimately involved in a number of other physiological and biochemical processes at cellular and systemic levels. DNA synthesis requires the activities of ribonucleotide reductase, an iron-dependent enzyme. Iron storage and metabolism are managed by key proteins within self-regulatory processes coded by short sequences of nucleotides found in the messenger RNA (mRNA), known as "iron response elements," in response to changing iron storage levels. In particular, *iron regulatory proteins* (IRPs) can bind to iron response elements and affect mRNA translation, thereby regulating the synthesis of specific proteins. Thus, iron binds to IRPs to a greater or lesser degree, depending on iron supply to influence relative levels of ferritin, the central iron storage protein; translation of mRNA that regulates enzymatic control of heme synthesis in immature RBCs; and synthesis of transferrin receptors. Iron is also a constituent of the enzymes that initiate the synthesis of serotonin and dopamine. Lastly, iron is essential in the synthesis of collagen and elastin.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Treatment of iron deficiency anemia constitutes the dominant use of supplemental iron within conventional medicine. Standard practice recognizes the increased risks of iron depletion associated with menstrual blood loss but typically responds only reactively and in the narrowest sense of anemia. Modern schools of natural medicine more often recognize the potential value of iron-rich foods and botanical preparations as a tonic therapy within a comprehensive strategy.

Historical/Ethnomedicine Precedent

In the classical medical tradition of Western culture, iron was considered the metal of Mars, and associated with vitality, the qualities of heat and fire, the blood, and inflammatory processes. Historically, traditions of natural medicine have emphasized enhancement of iron intake as part of a broader approach toward enriching the blood through provision of multiple minerals within the context of single herbs, herbal formulae, and nutrient-rich foods. Herbal formulae that "build the blood" have played central roles within many classical and folk herbal traditions around the world, especially in conjunction with strategies to regulate the menstrual cycle and improve hormonal balance, treat or prevent fatigue, and improve stamina and fertility.

Possible Uses

Alzheimer's disease, anemia, athletic performance (with deficiency only), attention deficit–hyperactivity disorder (ADHD), canker sores, celiac disease (with deficiency only), childhood cognitive development (with deficiency), cough, depression (with deficiency), dermatitis herpetiformis, human immunodeficiency virus (HIV) support, infertility (female) (with deficiency only), iron deficiency anemia, lactation support, menorrhagia (heavy menstruation) (with deficiency only), presurgery and postsurgery support (with deficiency, or after major surgery), pregnancy and postpartum support, restless legs syndrome (with deficiency).

Deficiency Symptoms

Iron deficiency is the most common nutrient deficiency in the United States (U.S.) and the world. Mild degrees of iron deficiency are common in U.S. toddlers, teenage girls, and women of childbearing age, although full-fledged iron deficiency anemia remains rare.[1] Most cases of iron deficiency appear according to well-known patterns of susceptibility, malnutrition, depletion, and exacerbation. Nevertheless, because of the numerous risk factors associated with excess iron intake, use of supplemental iron to prevent or treat any of these patterns associated with iron deficiency must be assessed based on individual characteristics, needs, and susceptibilities.

Although iron deficiency is the primary nutritional disorder among humans and perhaps the most studied form of nutritional deficit within conventional medicine, a comprehensive and coherent understanding of its effects and influences, both frank and subtle, immediate and long-term, is just beginning to

emerge into a coherent and comprehensive model. Iron deficiency anemia is the most overt and well-known symptom of iron deficiency. However, several gradations of iron depletion, including stages below the threshold and before the appearance of overt pathology, may contribute to physiological dysfunction and adversely affect quality of life. Thus, contrary to common assumptions, an individual does not have to be anemic to be iron deficient.[2] Furthermore, it is also critical to remember that iron deficiency anemia is not the only form of anemia, that other forms of anemia tend to appear in the same population(s), and that factors other than iron status contribute to iron deficiency anemia. In particular, folate and vitamin B_{12} status, as well as confounding factors such as drug-induced depletion patterns, must be considered to adequately diagnose suspected anemia.

Cellular responses to iron deprivation are poorly understood. Emerging evidence indicates that iron deficiency reprograms cellular genetic expression. Puig, Askeland, and Thiele[3] found that a deficiency of iron altered the expression of more than 80 genes in *Saccharomyces cerevisiae* (yeast) cells, which were chosen because of the similarity of their genome to that of humans. They observed that Cth2, a protein overproduced by iron-deficient cells, binds to the mRNA of over 80 genes and targets it for degradation or destruction by specifically down-regulating mRNAs encoding proteins that participate in many iron-dependent processes. Through this proposed mechanism, iron deficiency controls a posttranscriptional regulatory process that coordinately drives widespread metabolic reprogramming. The authors concluded: "We discovered that iron deprivation actually reprograms the metabolism of the entire cell. Literally hundreds of proteins require iron to carry out their proper function, so without this nutrient, there is a complete reorganization of how cellular processes occur."[3]

Iron deficiency may be modeled in the following three levels of increasing severity[4,5]:

1. Storage iron depletion. Tissue iron stores are depleted, but the functional iron supply is not limited.
2. Early functional iron deficiency. The supply of functional iron is low enough to impair RBC formation, but not sufficiently low to cause measurable anemia.
3. Iron deficiency anemia. Available iron is insufficient to support normal RBC formation, resulting in the microcytic and hypochromic anemia characteristic of iron deficiency. Both inadequate oxygen delivery due to anemia and suboptimal function of iron-dependent enzymes can produce symptoms at this more severe stage of iron deficiency.

Most of symptoms associated with iron deficiency result from the associated anemia; these include fatigue, weakness, pallor, tachycardia, palpitations, dyspnea on exertion, decreased endurance, and excess lactic acid production. Reduced hemoglobin and myoglobin levels associated with iron deficiency will impair physical exertion capacity and athletic performance by limiting oxygen delivery to tissues, reducing oxidative metabolism in mitochondria, diminishing mitochondrial content of cytochromes and other iron-dependent enzymes, and undercutting electron transport and ATP synthesis. Nonhematological effects resulting from iron deficiency include glossitis, taste bud atrophy, canker sores, nail spooning (koilonychia), brittle nails, hair loss, diminished immune function and increased susceptibility to infection, impaired intellectual performance, neurological dysfunction, and increased sensitivity to chill. Plummer-Vinson syndrome, characterized by the formation of webs of tissue in the throat and esophagus and difficulty swallowing, can occur in some advanced cases, possibly corresponding to a genetic predisposition. Children may also manifest behavioral disturbances such as attention deficit–hyperactivity disorder (ADHD) and breath-holding spells. Restless legs syndrome, initial seizure, pica, and pagophagia (excessive ice consumption, characterized in particular by chewing of ice) have also been associated with iron deficiency. Fatigue, weakness, anorexia, and pica may be caused by tissue depletion of iron-containing enzymes and not by decreased levels of blood hemoglobin.

Conditions contributing to iron deficiency, particularly from blood loss or malabsorption, include diarrhea, ulcers, ulcerative colitis, Crohn's disease, celiac disease, parasitic infections, hemorrhoids, GI cancers, menorrhagia, accidents, injuries, and surgery. Other factors influencing iron absorption and deficiency include hydrochloric acid secretion and gastric pH, decreased dietary intake, blood loss (both internal and external, as in menorrhagia), calcium intake, caffeine intake, high–phytic acid fiber foods, vitamin A, genetic variability, and iron storage levels.

Populations particularly at risk for compromised iron status include infants and children, age 6 months to 4 years, especially those living in inner cities or other impoverished circumstances; rapidly growing adolescents, especially females after menarche; pregnant women; individuals with acute or chronic blood loss due to medication-induced ulcers or intestinal parasites; frequent blood donors; individuals, especially children, with *Helicobacter pylori* infection (even without GI bleeding); populations exposed to environmental contaminants, especially lead; and individuals who engage in regular, intense exercise, particularly daily endurance training. All these factors are exacerbated in the context of ongoing menstrual cycles; menstruating women require approximately twice as much iron intake as men to replace their monthly losses due to menses. Although iron deficiency is not usually caused by a lack of iron in the diet alone, vegan or vegetarian diet or dietary intake may increase the risk of deficiency because of less relative bioavailability of iron from plant versus animal sources, at least in some individuals. Nutriture status of all nutrients, including iron, is compromised with poverty or lifestyle choices characterized by high intake of processed and refined foods or other forms of malnutrition.

Dietary Sources

The hemoglobin and myoglobin consumed within meat, poultry, oysters, and fish are the primary sources of heme iron in the diet. Approximately 40% of the iron in animal foods is heme iron and 60% is nonheme iron. Heme iron provides up to one third of total absorbed dietary iron, even though it accounts for only 10% to 15% of the iron potentially available in the diet. Nonheme iron is an inorganic compound, less easily absorbed, and derived from plant foods, dairy products, dried fruit, molasses, leafy green vegetables, and wine. Overall, absorption of heme iron can be up to 10 times that of nonheme iron, depending on whether body stores are replete. In the U.S., most grain products are fortified with iron. Iron fortification of cereal, using microencapsulated ferrous fumarate flakes, appears to achieve high iron bioavailability and can serve as an effective means of enhancing hemoglobin nutriture for infants and children.[6]

Many foods, beverages, and supplements have been shown to affect the bioavailability and absorption of iron. Foods that contain heme iron usually also provide nonheme iron, and the presence of the heme iron will enhance absorption of nonheme iron within the same foods or from foods consumed

concurrently. In contrast to heme iron, the absorption of which is influenced less by other dietary factors, the absorption of nonheme iron is strongly influenced by enhancers and inhibitors ingested at the same time. Iron absorption, especially nonheme iron, can be inhibited by concomitant intake of *phytate* (phytic acid, as found in unleavened wheat products, whole-wheat bran, wheat germ, oats, some rye crackers, nuts, beans, cacao powder, vanilla extract, and many other high-fiber foods), *tannins* (found in tea and coffee), *polyphenols* (as in green tea, rosemary, and red wine), calcium-rich foods, soy protein, and egg yolk. Conversely, the absorption of nonheme iron is also enhanced by concurrent ingestion of various organic acids, particularly ascorbic acid, but also citric, malic, tartaric, and lactic acids. Certain soy-containing foods (e.g., tofu, miso, tempeh), some soy sauces, vitamin A, and alcohol (other than red wine) can also increase iron absorption. In general, iron absorption from all forms may be influenced most by relative iron nutriture and storage status.

Ferrous salts are more efficiently absorbed than ferric salts. Acidic foods (e.g., tomato sauce) cooked in iron cookware may also provide a source of dietary iron, although not necessarily the optimal form. Alcohol, but not red wine, can increase the absorption of ferric, but not ferrous, iron.

Nutrient Preparations Available

Ferrous citrate, ferrous fumarate, ferrous gluconate, ferrous glutamate, ferrous glycinate, ferrous glycine sulfate, ferrous lactate, ferrous picolinate, ferrous succinate, ferrous sulfate; carbonyl iron; ferric sulfate.

A number of supplemental iron preparations are available, and different forms provide different proportions of elemental iron, with differing bioavailability characteristics. Ferrous fumarate is 33% elemental iron, ferrous sulfate (monohydrate) 33%, ferrous sulfate (heptahydrate) 23%, and ferrous gluconate 12% elemental iron. In general, absorption of elemental iron is very poor. Ferrous iron is much better absorbed than ferric iron. Heme iron is far better absorbed than nonheme. Absorption of organic chelates is probably the next highest, followed by organic salts (e.g., ferrous gluconate). Inorganic salts (e.g., ferrous sulfate) are the least well absorbed.

Diverse users absorb, tolerate, and respond to the various forms of iron to varying degrees and with differential responses. Iron supplements can be challenging to those who need to take them because when isolated, the nutrient is not easy to digest and can readily lead to nausea, constipation, or both. Nonheme iron is the predominant type of iron present in nutritional supplements. Ferrous forms (usually as the sulfate, gluconate, or fumarate salt) are readily absorbed without the need for acid. Although ferrous sulfate is the form of nonheme iron used most frequently, ferrous succinate is more often recommended. Ferrous fumarate and iron-EDTA may be more bioavailable than ferrous sulfate, particularly in individuals with low (or impaired) gastric acidity. Enteric coating is sometimes used with ferrous sulfate to delay tablet dissolution and moderate adverse effects, but bioavailability may be compromised. Combining iron with certain mineral-rich herbs, such as yellow dock (*Rumex crispus*), dandelion root (*Taraxacum officinale*), alfalfa leaf (*Medicago sativa*), and nettles tops (*Urtica dioica*), may enhance absorption, buffer irritant effects, and expand the nutritive effect beyond iron alone.

Dosage Forms Available

Capsule; capsule, time-release; liquid; tablet.

Intravenous (IV) iron forms: Iron dextran (DexFerrum, Imferon), iron sucrose (Venofer), sodium ferric gluconate (Ferrlecit).

Source Materials for Nutrient Preparations

Most are inorganic and organic salts, chelates, and synthetic polymeric matrices. Botanical extracts of iron-rich plants. Some heme iron concentrates have been used in clinical trials, but generally are not commercially available.

Dosage Range

The doses of iron discussed in this monograph represent elemental iron unless stated otherwise.

Adult

Dietary: In the U.S. the average adult daily diet of premenopausal and postmenopausal women provides 12 mg/day and of pregnant women about 15 mg/day. In the United Kingdom (U.K.) the average daily dietary intake for adult women is 12.9 mg/day. For men in the U.S. the average adult daily diet provides 16 to 18 mg elemental iron daily; in the U.K., 14.5 mg.
Supplemental/Maintenance:

Men: 8 mg/day
Women, nonpregnant, nonlactating, age 19 to 50 years: 18 mg/day
Women, age 19 to 51 and older: 8 mg/day

During pregnancy, the metabolic needs of the developing fetus and placenta, as well as a significant expansion of blood volume, increase iron utilization. Conversely, iron requirements are potentially reduced during pregnancy by cessation of menstruation and increased efficiency of absorption. Consequently, iron intake may not need to be any greater than for other adult women, and routine iron supplementation is not necessarily required in pregnancy. Nevertheless, within context of care by a qualified health care professional, pregnant women may benefit from iron supplementation during the last 3 to 6 months of pregnancy. In particular, prenatal prophylactic iron supplementation before 20 weeks' gestation may help pregnant women increase the birth weight of their infants.[7] Iron status should be monitored in all pregnant women.

In general, routine supplementation of iron on a daily basis is not recommended. It is generally advised that use of iron supplements be avoided unless clinically indicated, such as low serum ferritin or microcytic, hypochromic anemia. Excess iron has been implicated in free-radical damage. These cautions do not extend consumption of iron-rich foods in moderation for most individuals. Notably, the dietary iron intake of the majority of premenopausal and pregnant women in the U.S. is lower than the recommended dietary allowance (RDA) and the dietary intake of many men is greater than the RDA. Many multivitamin-mineral preparations contain 18 mg of iron, which may result in excessive iron intake for certain individuals.
Pharmacological/Therapeutic: 10 to 200 mg/day.

In treatment of iron deficiency, 100 mg/day is a common recommended amount for an adult; dosage is generally reduced after the frank deficiency is corrected. Administration of therapeutic levels is generally recommended for 3 to 4 months after correction of iron deficiency anemia, to replace iron stores.
Toxic: 100 mg/day (in absence of iron deficiency).

The tolerable upper intake level (UL) for iron is 45 mg/day for non-iron-deficient adolescents and adults over age 14 years, including pregnant and breastfeeding women, according to

standards set by the Food and Nutrition Board (FNB) of the U.S. Institute of Medicine. This UL is based on the prevention of GI distress and is generally understood not to apply to individuals being treated with iron under supervision of a qualified health care professional.

Pediatric (<18 Years)

Dietary (AI, adequate intake):

Infants, birth to 6 months: 0.27 mg/day (AI, adequate intake)
Infants, 7 to 12 months: 11 mg/day (AI)
Children, 1 to 3 years: 7 mg/day (AI)
Children, 4 to 8 years: 10 mg/day (AI)
Children, 9 to 13 years: 8 mg/day (AI)
Adolescents, 14 to 18 years: 15 mg/day (for females); 11 mg/day (for males)

Supplemental/Maintenance: Otherwise-healthy infants born without iron deficiency benefit from iron supplementation, according to the findings of an intervention trial.[8]
Pharmacological/Therapeutic: 10 to 50 mg/day, depending on body weight, condition, and other individual factors, under medical supervision.
Toxic: 2.0 to 2.5 g can be lethal in a 10-kg child. Deaths in children have occurred from ingesting as little as 200 mg to as much as 5.85 g of iron.[9]

Laboratory Values

Current diagnostic markers for iron deficiency are not highly sensitive, unless the deficiency is severe. Bone marrow iron is often considered the "gold standard" of iron stores but is rarely practical in most clinical situations. Serum ferritin concentration provides the most accurate diagnostic method to assess iron stores and confirm iron deficiency, but only if the values are low. Iron deficiency can accompany elevated serum ferritin levels when acute or chronic inflammatory states are present, because ferritin is one of the acute-phase reactants.

One can traditionally obtain a serum iron and serum iron-binding capacity and divide the former by the latter to determine the transferrin saturation. If iron/iron-binding capacity is less than 10%, there is a probability of iron deficiency. A more modern approach to this diagnosis is to measure the serum ferritin; iron deficiency can usually be excluded as a diagnosis if serum ferritin is more than 220 µg/L. However, if it is less than 220, it is judicious to obtain a serum transferrin receptor (sTfR) level. This measures the soluble receptors of transferrin in the circulation, receptors that bind to the available iron. If this value is 28 mg/L or higher, there is a significant probability of iron deficiency.[10] Ongoing developments in knowledge of how iron deficiency influences cellular genetic expression may soon provide diagnostic markers of increased sensitivity by pinpointing the genes affected by iron deprivation to provide a genetic fingerprint of how varying levels of iron deprivation are expressed in different patients.[3]

It is often necessary to assess ferritin, percentage transferrin saturation, and sTfR levels for an accurate assessment of iron status, because ferritin can be falsely elevated by a number of conditions, including pregnancy, inflammatory conditions (e.g., arthritis), malignancy, skin conditions, irritable bowel disease, and acute/chronic infections, both viral and bacterial.

Areas to exclude as causes of anemia include iron deficiency anemia, nutritional anemias due to B_{12} and folic acid deficiency, drug-induced anemia, alcohol-induced bone marrow toxicity, acute and chronic hemolysis, other illnesses affecting RBC production, and malignant infiltration of the bone marrow.

Serum Ferritin

Normal: 12 to 200 µg/L.

Serum ferritin is the measure of iron status that provides the most accurate indicator of tissue stores and can serve as an effective screening tool. However, it can be elevated with inflammation or infection independent of iron status. Serum ferritin greater than 225 µg/L can generally be interpreted as ruling out iron deficiency anemia. When serum ferritin is less than 220 µg/L, the soluble transferrin receptor (sTfR) level can be used to determine if the patient has upregulated transferrin receptors. Some practitioners of natural therapeutics recommend that males ideally should not have a ferritin level much more than 80 µg/L, unless they are actively engaged in strenuous athletic training or exercise regimens, to minimize iron-catalyzed oxidative stress.

Serum Iron

Normal: 9 to 29 mmol/L.

Serum iron provides an insensitive indicator of iron status, declining only after tissue stores are completely exhausted.

Transferrin Saturation

Transferrin saturation of less than 16% of available binding sites indicates iron deficiency.

Some practitioners of natural therapeutics recommend that transferrin saturation not be greater than 45%, especially with a history of heart disease, diabetes, or cancer. Transferrin saturations greater than 60% are highly suggestive of hereditary hemochromatosis, or another form of iron overload, and should be thoroughly investigated with genotyping and/or liver biopsy to assess hepatic iron stores.

Serum Transferrin Receptor

Also known as soluble transferrin receptor (sTfR). Levels greater than 8 mg/L indicate deficiency in standard diagnostic usage. However, some experienced practitioners of nutritional therapeutics use 28 mg/L as the level for demarcating iron deficiency. Values greater than 28 mg/L are also consistent with iron deficiency with corrections for altitude.

Measurement of serum transferrin receptor is a new marker of iron metabolism that reflects body iron stores and total erythropoiesis. Unlike serum ferritin, the sTfR is not an acute-phase reactant, so it is not elevated in response to acute or chronic inflammatory disease.[10] Thus, it serves as a reliable marker of iron status when iron deficiency is associated with chronic disorders, such as inflammation, infection, or malignancy. In situations of iron deficiency, the avidity and number of soluble transferrin receptors (i.e., sTfR) increases in proportion to tissue iron deficit. Thus, soluble TfR levels are decreased in situations characterized by diminished erythropoietic activity and are increased when erythropoiesis is stimulated by hemolysis or ineffective erythropoiesis. Measurements of sTfR are very helpful in investigating the pathophysiology of anemia, quantitatively evaluating the absolute rate of erythropoiesis and the adequacy of marrow proliferative capacity for any given degree of anemia, and to monitor the erythropoietic response to various forms of therapy, in particular allowing one to predict the response early, when changes in hemoglobin are not yet apparent. Iron status also influences sTfR levels, which are considerably elevated in iron deficiency anemia but remain normal in the anemia of inflammation, and thus may be particularly valuable in the differential diagnosis of microcytic anemia, especially when identifying concomitant iron deficiency in a patient with inflammation, because ferritin values are then generally normal. Elevated sTfR levels are also

the characteristic feature of functional iron deficiency, a situation defined by tissue iron deficiency despite adequate iron stores. The sTfR/ferritin ratio can thus describe iron availability over a wide range of iron stores. With the exception of chronic lymphocytic leukemia (CLL), high-grade non-Hodgkin's lymphoma, and possibly hepatocellular carcinoma, sTfR levels are not increased independent of iron status in patients with malignancies.[11]

Erythrocyte Protoporphyrin

Recent research indicates that erythrocyte protoporphyrin (EP) can provide a useful screening tool for determining iron deficiency. Using the receiver operating characteristic (ROC) curve to characterize the sensitivity and specificity of hemoglobin and EP measurements in screening for iron deficiency, Mei et al.[12] found EP "consistently better than measurements of hemoglobin for detecting iron deficiency" in preschool children, age 1 to 5 years. However, in nonpregnant women, they found "no significant difference between EP and hemoglobin in ROC performance for detecting iron deficiency."

SAFETY PROFILE

Overview

Adverse effects resulting from ingestion of iron supplements occur frequently and often manifest with common dosage levels. However, iron toxicity is relatively rare and predominantly occurs acutely as a result of overdose. In the U.S., iron is the leading cause of accidental poisonings in children. In response, child-resistant safety packaging is legally required for all iron-containing products. Even so, the incidence of iron poisonings in young children increased dramatically in 1986. Many of these children obtained the iron from a child-resistant container opened by themselves or another child, or left open or improperly closed by an adult.[13]

Nutrient Adverse Effects

General Adverse Effects

In adults, early symptoms of supplemental iron toxicity include GI irritation, nausea, vomiting, and abdominal pain. Constipation is the most frequently reported adverse effect associated with some forms of iron, even when therapeutically indicated, and may lead to fecal impaction, particularly in the elderly. Conversely, an exacerbation of diarrhea can occur in individuals with inflammatory bowel disease and may be accompanied by bleeding. Liquid iron preparations may blacken the teeth. Signs and symptoms of overload include grayish skin, headache, shortness of breath, fatigue, dizziness, and weight loss. More advanced toxic effects associated with acute excessive iron intake include weakness, fatigue, pallor, arrhythmia, tachycardia, cardiovascular collapse, cyanosis, seizures, and coma.

Intravenous iron, administered in some cases of severe anemia in an inpatient setting, can lead to headache, fever, lymphadenopathy, joint pain and inflammation, hives, exacerbation of rheumatoid arthritis, hemolytic reactions (often associated with acute back pain and renal injury), and (rarely) anaphylaxis.

Adverse Effects Among Specific Populations

Individuals with insulin resistance syndrome, diabetes, or hepatitis C may be particularly susceptible to iron overload. Iron overload triples mortality in people with elevated transferrin saturation.[14]

Supplementing iron can be quite dangerous for individuals with hereditary hemochromatosis, hemosiderosis, polycythemia, iron-loading anemias, and other conditions involving excessive storage of iron. Excessive absorption of iron from dietary sources may occur in response to excessive formation of red blood cells. *Hereditary hemochromatosis* (HH) is a genetic disorder that affects up to 1 in 200 individuals of northern European descent and is characterized by increased intestinal absorption of iron leading to progressive deposition of iron-containing pigments in the liver and other tissues. If untreated, tissue iron accumulation may lead to bronzing of skin, cirrhosis, cardiomyopathies, diabetes, conduction irregularities, testicular atrophy, and arthritis. The HFE gene and the mutation resulting in HH were identified in 1996, but the precise role of the protein encoded by the HFE gene in intestinal iron absorption has yet to be fully elucidated.[15,16] Supplemental iron is generally contraindicated in individuals with HH, but they are usually not advised to avoid iron-rich foods, depending on their degree of iron overload at diagnosis and their response to iron unloading on repeated phlebotomies. Sub-Saharan African hemochromatosis is a variant that appears to require both high iron intake and an as-yet unidentified genetic factor.[17]

Hemosiderosis is characterized by excessive iron deposits in hemosiderin, the normal iron storage protein. Long-term use of iron at high dosage levels can cause hemosiderosis that clinically resembles hemochromatosis.

Patients with sideroblastic anemia, pyruvate kinase deficiency, thalassemia major, and similar conditions are particularly at risk of iron overload when treated for anemia with numerous transfusions. Iron overload is significantly less common in individuals with hereditary spherocytosis and thalassemia minor, unless they are administered excessive amounts of iron after being misdiagnosed as iron deficient. Emerging information suggests the existence of a Mediterranean form of hemochromatosis, not involving the HFE gene, and with a genetic association unknown at this time, distinct from HH and thalassemias. Treatment for iron overload is by phlebotomy, typically weekly removal of 500 mL of blood until mild iron deficiency is induced. Transfusion-dependent states, however, require iron chelation, generally with regular overnight subcutaneous infusions of deferoxamine mesylate (Desferal).

In a randomized, placebo-controlled trial involving children age 1 to 35 months living in Zanzibar, Sazawal et al.[18] found that "supplementation with iron and folic acid in preschool children in a population with high rates of malaria can result in an increased risk of severe illness and death." Routine prophylactic iron supplementation in such situations should be avoided pending further research. However, within the context of an active program "to detect and treat malaria and other infections, iron-deficient and anaemic children can benefit from supplementation."

Pregnancy and Nursing

Low-dose iron supplements are generally safe and effective in pregnancy.[19] Iron supplementation during pregnancy and lactation should be undertaken only under the supervision of a health care professional trained and experienced in nutritional therapeutics.

Infants and Children

Infants and children are especially vulnerable to iron toxicity. Doses as low as 60 mg/kg can be fatal.

Contraindications

Iron preparations are generally contraindicated for individuals diagnosed with a variety of conditions, including hemochromatosis, hemosiderosis, transfusion-dependent thalassemia or other transfusion-dependent states, other conditions associated with iron overload, peptic ulcer, inflammatory bowel disease or other GI disease, diverticulitis, and intestinal stricture. Patients receiving hemodialysis for end-stage renal disease (ESRD) are particularly susceptible to oxidative stress and carotid artery intima media thickening as a result of iron administration, especially without concomitant vitamin E.[20,21]

Prophylactic iron (and folic acid) may be contraindicated for children in malarial environments.[18]

Iron supplements are generally inappropriate for individuals with a history of any unusual or allergic reaction to iron, or medicines, foods, dyes, or preservatives containing iron.

Precautions and Warnings

Conservative principles of practice suggest that regular iron supplementation be avoided in any individual who has not demonstrated iron deficiency anemia or low iron stores. Such caution is warranted because of the frequency of undetected HH, the pervasive pathophysiology of inflammation and oxidative stress, and emerging concerns about the more subtle effects of chronic excess iron intake. Chronic iron administration increases vascular oxidative stress and accelerates arterial thrombosis.[22] Thus, for example, iron supplementation appears particularly to increase risks of vascular disease and thrombosis for smokers with hypercholesterolemia.[23]

Some patients have a serious allergic reaction to IV iron dextran (Imferon), and therefore patients must be monitored especially closely during the first two Imferon administrations using a test dose of 25 mg for each session. After the second test dose is given, the administered dose can be increased to 100 mg. Intravenous sodium ferric gluconate (Ferrlecit) does not contain dextran, and this significant concern regarding anaphylactic reactions is essentially negligible.

Numerous researchers and reviewers have proposed, and sometimes proved, links between excess iron and the development or exacerbation of numerous pathological conditions, including increased risk of infection and inflammatory processes (e.g., pulmonary tuberculosis, pelvic endometriosis), heart disease (e.g., carotid atherosclerosis, coronary disease, myocardial infarction), autoimmune processes (e.g., diabetes, rheumatoid arthritis, systemic lupus erythematosus), neurodegenerative diseases (e.g., Alzheimer's disease, Parkinson's disease, Huntington's disease), and cancer (especially hepatocellular carcinoma and colorectal cancer).[23-46] Most of these associations are not conclusively supported by a review of well-done human studies, and some have been disproved, but many are consistent with known patterns of physiology, epidemiology, and pathogenesis. This important area of conflicting data, experience, and opinions will undoubtedly continue to be the subject of clinical trials and meta-analyses.

INTERACTIONS REVIEW

Strategic Considerations

Iron deficiency is the most common micronutrient deficiency in the world, and iron is the nutrient most often prescribed by conventional physicians as an active therapeutic intervention. However, the principles underlying and clinical practices framing such administration have not yet matured into a comprehensive and coherent approach for safe and effective prescribing in daily clinical practice. As with the inflammation it can induce and the free radicals it often generates, the classical metaphor of iron as a "hot" mineral can be applied therapeutically, serving well in suitable circumstances at the appropriate amounts, but just as easily causing a ripple of multiple adverse effects when insufficient, excessive, or simply inappropriately situated. Given the risks of iron depletion and iron overload and the multiple interaction patterns involving iron, deeper analysis of the research data and clinical practices reveals that universal declarations of efficacy, risk, and response patterns do not adequately convey the complexity of individual variability, patient subgroups, and conflicting needs. Thus, iron exemplifies the need for personalized and evolving therapeutic strategies within an integrative model when multiple therapies and coordinated care among various health care providers are involved.

Iron might be seen as a warrior whose sword cuts both ways. It produces heat, agitation, and invigoration, which can convey vitality, sustain activity, and embody vigor, but also carries the risk of oxidative stress, irritation, inflammation, and infection. Although iron depletion is common and has been given more attention than any other nutrient deficiency in conventional medical practice, the methods of evaluation and the standards for augmentation (or reduction) remain controversial. Depleted tissue iron stores are often missed in susceptible individuals because the clinical focus almost exclusively centers on frank iron deficiency anemia rather than functional parameters. Conversely, iron excess or overload, or even inappropriately timed administration, will tend to increase susceptibility to, or aggravate inflammatory processes and promote an environment favorable to, pathogenic microorganisms. The physiological response to infection and neoplasm is to make iron as unavailable as possible to the invading cells, which results in the functional iron deficiency, often seen with acute or chronic infections, and malignancies. Although not rigorously investigated with careful clinical research, much clinical experience suggests that it is often unwise to override this physiological adaptation with oral, and particularly parenteral, iron administration.

Accurate laboratory evaluation of iron status is multifactorial, often making it difficult and elusive to assess functional iron levels, metabolic processes, and depletion and overload states. It is often necessary to assess ferritin, percentage transferrin saturation, and sTfR levels for an accurate assessment of iron status, because ferritin can be falsely elevated by a number of conditions, including pregnancy, inflammatory conditions (e.g., arthritis), malignancy, skin conditions, irritable bowel disease, and chronic infections, both viral and bacterial.

Many minerals and metals are known to bind with a wide range of medications to form insoluble complexes that impair absorption and bioavailability, but with no other common nutrient as much as with the iron salts. Although this phenomenon has been studied widely, the body of evidence indicates that adverse effects on therapeutic efficacy of either agent involved can usually be effectively avoided by separating oral intake by at least 2 hours. Nevertheless, direct inquiry and frank discussion with patients regarding supplement use is critical because simultaneous intake over an extended period could adversely impact therapeutic action and confuse monitoring. Further, unsupervised alterations in intake habits, especially sudden discontinuation of iron that had been taken simultaneously, could result in a rapid elevation in effective dose levels of other agents, thus creating unintended consequences. As always, physician-patient communication, interdisciplinary

collaboration, and reinforcement of trust, honesty, and respect for patient choices will always enhance the therapeutic process and support positive clinical outcomes.

The volatility of iron within human physiology, its complex interactions with a wide range of medications and nutrients, and the adverse implications of not maintaining dynamic equilibrium all attest to the critical importance of attentiveness to the changing needs of the individual patient whenever dealing with iron, its intake, and reverberations throughout the economy of the organism.

NUTRIENT-DRUG INTERACTIONS

Acetylsalicylic Acid (Aspirin)

Acetylsalicylic Acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Effect and Mechanism of Action

Aspirin's activity in inhibiting the effects of cyclooxygenase (COX) extends beyond those functions involved in inflammatory responses. In the stomach the enzyme's products build bicarbonate and mucus buffers against stomach acidity, without which the risk of ulceration can increase 20-fold. Gastrointestinal (GI) bleeding caused by aspirin results in iron loss, which can create a state of iron deficiency if aspirin is taken regularly. Iron supplementation can reverse iron depletion induced by aspirin-related blood loss.

Research

In a 1973 study involving 13 healthy subjects, Leonards et al.[47] demonstrated that sodium salicylate tablets and aspirin tablets caused GI bleeding and that the blood loss in volunteers administered aspirin was appreciably greater (5.6 vs. 1.2 mL/day above control values).[47] Subsequently, Palme and Koeppe[48] compared the GI blood loss caused by the acetylsalicylic acid (ASA) and benorilate (4-acetamidophenyl-2-acetoxybenzoate, Benortan) in Wistar rats and human subjects by measuring the total body iron retention. Their findings indicate that the daily iron loss under ASA is significantly higher (almost doubled) than that under benorilate.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Chronic aspirin ingestion is a frequent cause of iron deficiency and anemia. Gastrointestinal bleeding is a universal and virtually unavoidable adverse effect associated with aspirin consumption. It can cause ulcerations, abdominal burning, pain, cramping, nausea, gastritis, and even serious GI bleeding and liver toxicity. Sometimes, stomach ulceration and bleeding can occur without abdominal pain. Black tarry stools, weakness, and dizziness on standing may be the only signs of internal bleeding. Often there are no externally observable symptoms or obvious blood in the stool.

Physicians prescribing aspirin, or working with patients who self-administer analgesics, are advised to be alert to signs of GI blood loss and iron depletion caused by aspirin intake. Likewise, it is essential to inform patients that aspirin, in any amount, causes gastric bleeding to some degree and to educate them regarding the associated risks. In general, iron supplementation should not be undertaken, and should be actively discouraged, unless iron deficiency has been clinically established. More broadly, patients may benefit from discussing the limitations of protracted palliative therapy for chronic pain and inflammation and engaging in the process of identifying and addressing the causes of pain within a more fundamental and proactive long-term therapeutic strategy.

Iron deficiency anemia (IDA) is readily identified by a low hemoglobin and serum ferritin concentration, although it is not excluded by a normal serum ferritin. Serum transferrin receptor measurements can provide a useful alternative for distinguishing IDA from the anemia of chronic disease because the serum receptor concentration is usually elevated in patients with IDA but normal in patients with anemia from inflammation or neoplasia. Screening for fecal occult blood is prudent with suspected GI blood loss, even when the suspicion of physiological IDA from other known risk factors is high. A gastric delivery system for oral iron that eliminates nausea and vomiting and improves iron absorption when given with food may be appropriate with patients who experience adverse effect from oral iron supplements.

Angiotensin-Converting Enzyme (ACE) Inhibitors

Evidence: Captopril (Capoten), enalapril (Vasotec).

Extrapolated, based on similar properties: Benazepril (Lotensin); combination drug: benazepril and amlodipine (Lotrel); captopril combination drug: captopril and hydrochlorothiazide (Acezide, Capto-Co, Captozide, Co-Zidocapt); cilazapril (Inhibace); enalapril combination drugs: enalapril and felodipine (Lexxel), enalapril and hydrochlorothiazide (Vaseretic); fosinopril (Monopril), lisinopril (Prinivil, Zestril); combination drug: lisinopril and hydrochlorothiazide (Prinzide, Zestoretic); moexipril (Univasc), perindopril (Aceon), quinapril (Accupril), ramipril (Altace), trandolapril (Mavik).

Evidence, iron forms: Ferric gluconate, ferrous sulfate.

Extrapolated, iron forms, based on similar properties: Iron dextran complex, iron sucrose.

Nutrient forms with similar properties but evidence lacking for extrapolation: Ferrous fumarate, ferrous gluconate, polysaccharide-iron complex.

Effect and Mechanism of Action

Supplemental iron salts may diminish absorption and bioavailability of ACE inhibitors, and vice versa. The mechanism of this interaction has yet to be fully elucidated but is likely caused, at least in part, by binding within the intestines to form a poorly absorbed stable chelation complex.[49] Dry cough, and resultant patient nonadherence, is the most common limiting factor of ACE inhibitors. The mechanism that induces ACE inhibitor–induced dry cough involves inhibition of the metabolism of inflammatory proteins known as *kinins* (e.g., bradykinin), but it has not yet been fully elucidated. Another contributing factor to ACE inhibitor–induced cough may be the increased generation of nitric oxide (NO), which acts as a proinflammatory substance on bronchial epithelial cells. Iron coadministration inhibits cough associated with ACE inhibitors, most likely by acting as an inhibitor of NO synthase activity in bronchial epithelial cells. The erythropoietin-lowering effects of enalapril treatment may also aggravate anemia in renal transplant recipients. Concomitant iron might reverse this adverse effect but can increase risks of oxidative stress if given without counterbalancing antioxidant support. However, ACE inhibitors may enhance the adverse effect and toxicity of iron salts, particularly administered parenterally. Outside the specific context of ACE inhibitor therapy, administration of intravenous (IV) iron to anemic patients on hemodialysis can lead to an "oversaturation" of transferrin, and as a result, non-transferrin-bound, redox-active iron can induce lipid peroxidation.[20]

Research and Reports

In a double-blind, placebo-controlled, crossover study involving seven healthy adult volunteers, Schaefer et al.[49a] observed that concomitant administration of captopril (25 mg) and ferrous sulphate (300 mg) resulted in a 37% decrease in area under the curve (AUC) plasma levels for unconjugated captopril compared with placebo. The authors suggested that the observed decrease could be caused by an interaction in the GI tract subsequent to simultaneous ingestion.

Dry cough has been reported to occur in 5% to 39% of patients undergoing ACE inhibitor therapy, and in most cases the drug needs to be discontinued because of this adverse effect. Lee et al.[50] conducted a randomized, double-blind, placebo-controlled trial involving 19 patients who had developed ACE inhibitor–induced cough to determine if iron could ameliorate the cough, hypothetically by inhibiting NO-induced inflammation of bronchial epithelial cells. After an initial 2-week observation period, the subjects were randomized to a daily morning dose of 256 mg ferrous sulfate as a tablet or placebo for 4 weeks. The researchers evaluated data from cough diaries, scoring the daily severity of the symptom, as well as blood cell count and serum iron and ferritin concentration between the two periods. Mean daily cough scores during the observation and treatment periods showed a significant reduction in cough scores with iron coadministration but not with placebo. Three subjects in the iron group demonstrated almost complete cough abolition. Interestingly, the authors reported no significant changes in laboratory data in either group.

A bimodal pattern of interaction appears to occur with the administration of IV iron in patients being treated with ACE inhibitors, particularly in the context of hemodialysis. In several studies of hypertensive patients with renal failure (or transplant) on dialysis, mild exacerbation of anemia has been observed during treatment with enalapril.[51-54] Gossmann et al.[55] have suggested that ACE inhibitor–related anemia in renal transplant recipients seems to result from the erythropoietin-lowering effect of this group of drugs. However, administration of iron salts presents numerous risks in this patient population. During a 13-month period, Rolla et al.[56] reported aggravated adverse effects, including erythema, abdominal cramps, nausea, vomiting, and hypotension, in three enalapril-treated patients after IV ferric gluconate administration. During that same period, 15 other patients, none of whom were undergoing ACE inhibitor therapy, demonstrated no similar adverse events while receiving IV ferric gluconate. The authors suggested that enalapril might exaggerate the known adverse effects of IV iron by inhibiting the degradation of bradykinin, substance P, or other presumed inflammatory mediators of such iron-related effects. Notably, coadministration of vitamin E may attenuate oxidative stress induced by IV iron in patients on hemodialysis. In a randomized crossover design involving 22 patients, Roob et al.[20] investigated the effects on lipid peroxidation of 100 mg iron(III) hydroxide–sucrose complex, either with or without a single oral dose of 1200 IU of all-racemic alpha-tocopheryl acetate administered 6 hours before hemodialysis. They observed that vitamin E supplementation led to a 68% increase in plasma alpha-tocopherol concentrations and significantly reduced the AUC (0-180 minutes) of plasma malondialdehyde (MDA) to cholesterol and peroxides to cholesterol ratios. These findings suggest that an integrative strategy using several nutrients, such as ascorbic acid, folic acid, beta-carotene, and vitamin E, acting as an antioxidant network might serve to buffer potential adverse effects of IV iron salts and potentially enhance overall treatment outcomes in patients undergoing hemodialysis, particularly with concomitant ACE inhibitors. Further research in the form of well-designed clinical trials may be warranted to test these possible synergies.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing ACE inhibitors are advised to educate patients regarding the risk of adverse effects, including drug-induced cough and anemia, and to inform them that coadministration of an oral iron supplement may reduce such symptoms. However, to avoid absorption problems inhibiting bioavailability of both substances, patients should wait at least 2 hours after administration of the medication before taking iron.

Supplementation of any minerals by patients with renal failure or on dialysis can be dangerous and should only be done within the context of close medical supervision. Patients receiving ACE inhibitor therapy may experience an exaggeration of adverse effects often associated with IV administration of iron salts; monitor closely for adverse effects such as nausea, vomiting, and hypotension.

Antacids and Gastric Acid–Suppressive Medications

Antacids: Aluminum carbonate–gel (Basajel), aluminum hydroxide (Alternagel, Amphojel); combination drugs: aluminum hydroxide, magnesium carbonate, alginic acid, and sodium bicarbonate (Gaviscon Extra Strength Tablets, Gaviscon Regular Strength Liquid, Gaviscon Extra Strength Liquid); aluminum hydroxide and magnesium hydroxide (Advanced Formula Di-Gel Tablets, co-magaldrox, Di-Gel, Gelusil, Maalox, Maalox Plus, Mylanta, Wingel); aluminum hydroxide, magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); calcium carbonate (Titralac, Tums); magnesium hydroxide (Phillips' Milk of Magnesia MOM); combination drugs: magnesium hydroxide and calcium carbonate (Calcium Rich Rolaids); magnesium hydroxide, aluminum hydroxide, calcium carbonate, and simethicone (Tempo Tablets); magnesium trisilicate and aluminum hydroxide (Adcomag trisil, Foamicon); magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); combination drug: sodium bicarbonate, aspirin, and citric acid (Alka-Seltzer).

Histamine (H_2) receptor antagonists:
Evidence: Cimetidine (Tagamet; Tagamet HB).
Extrapolated, based on similar properties: Famotidine (Pepcid RPD, Pepcid, Pepcid AC), nizatidine (Axid, Axid AR), ranitidine (Zantac); combination drug: ranitidine, bismuth, and citrate (Tritec).
Similar properties but evidence lacking for extrapolation:
Proton pump inhibitors: Esomeprazole (Nexium), lansoprazole (Prevacid, Zoton), omeprazole (Losec, Prilosec), pantoprazole (Protium, Protonix, Somac), rabeprazole (AcipHex, Pariet).

Effect and Mechanism of Action

The mechanisms proposed vary with the agent in question and the form of iron involved. All iron-antacid interactions are affected by the physiological premise that hydrochloric acid in the stomach reduces ferric iron to ferrous iron, the required form for absorption. By inhibiting acid secretion or neutralizing the normally acidic gastric environment, acid-suppressive agents will tend to reduce the absorption of dietary iron. Conversely, the iron status of patients with iron depletion due to internal bleeding from ulcers could also benefit from the therapeutic action of such medications. Finally, iron and some medications can bind to each other and inhibit absorption of both agents.

Scientific knowledge of the full set of factors and mechanisms involved in the various interactions in question is limited, inconsistent, and often of questionable relevance to clinical practice. In vitro experiments investigating the interactions of oral hematinics and antacid suspensions indicate that aluminum hydroxide can precipitate iron as hydroxide and ferric ions become intercalated into the aluminum hydroxide crystal lattice.[57] Carbonates can interact with iron to form poorly soluble iron complexes.[58] Ferrous sulfate can change into less easily absorbable salts, or its polymerization may increase, in the presence of magnesium trisilicate.[59] Histamine (H_2) receptor antagonists (H_2RAs) appear to be more problematic than other antacids, at least in light of currently available evidence. Cimetidine, and probably to a lesser extent ranitidine, can potentiate the action of oral anticoagulants of both coumarin and indanedione structure, through a dose-dependent, reversible inhibition of cytochrome P450, and if international normalized ratio (INR) is not closely monitored and adjusted appropriately, can cause hemorrhagic complications that further compromise iron status.[60] Furthermore, H_2RAs are considered efficient chelators of Fe^{2+}, and each agent will decrease absorption of the other by binding iron in the GI tract.[61] More recently, there has been concern that long-term use of proton pump inhibitors (PPIs) might impair the normal hematological process and result in iron deficiency by reducing stomach acid levels.

The adverse effect on absorption of food from iron, particularly ferric nonheme forms as found in plants and dairy products, is likely to be greater than from most iron contained in supplements, which is more often of the ferrous form and is readily absorbed without the need for acid. The degree and clinical significance of this interaction can be influenced by genetics, iron source, concomitant food constituents, timing of intake, duration of medication use, digestive health, aging, and other factors.

Research

A wide range of experimental and clinical studies in the scientific literature have reported that pharmacologically reducing the acidity of the gastric environment will inherently impair normal gastric function and inhibit absorption of iron and, to a lesser degree, zinc, calcium, and other minerals.[62-67] Although the basic theme of impaired acidity underlies all permutations involved, the evidence cannot easily be analyzed as a coherent data set because of a variety of confounding factors, including significant variety in forms of iron used, iron doses ranging from minimal to relative overdoses, variable mechanism of action and dose of medications, initial iron status and medical conditions (or health) of subjects, the history and severity of any pathology present, lack of dietary consistency, and durations of treatment ranging from experimental single administrations to extended periods representative of clinical practice. Timing of intake and duration of use appear to influence the clinical significance of the interaction to the greatest degree.

Aluminum Hydroxide, Calcium Carbonate, Magnesium Hydroxide, Magnesium Trisilicate, Sodium Bicarbonate, and Combinations. Most experiments have assessed short-term pharmacokinetic effects of simultaneous iron and antacid administration. In an experiment involving iron-replete healthy subjects, Benjamin et al.[58] (1967) and Rastogi et al.[68] (1976) observed poor absorption of iron in the presence of sodium bicarbonate or aluminum hydroxide, respectively. Ekenved et al.[69] found that an antacid containing aluminum and magnesium hydroxides along with magnesium carbonate reduced absorption of ferrous sulfate and ferrous fumarate (both containing 100 mg ferrous iron) by 37% and 31%, respectively. Hall and Davis[59] administered magnesium trisilicate (35 g) to nine subjects, who were given 5 mg of isotopically labeled ferrous sulfate (5 mg), and observed a reduction in iron from 30% to 12% on average but from 67% to 5% in one individual. In 1986, O'Neil-Cutting and Crosby[70] published findings from a small-dose iron tolerance test involving 22 mildly iron-deficient

(menstruation or blood donation) but healthy subjects to compare absorption of iron with and without various antacids. They found that sodium bicarbonate (1 g) and calcium carbonate (500 mg) caused the plasma iron increase to decline by 50% and 37% compared with the controls, respectively, except when the calcium carbonate was present in a tableted multivitamin-mineral formulation. The authors suggested that the competitive binding of iron by ascorbic acid in the multivitamin-mineral tablet facilitated uninhibited absorption of the iron. In contrast, they observed that 1 teaspoonful of a magnesium hydroxide/aluminum hydroxide antacid did not significantly decrease absorption at 2 hours of simultaneously ingested iron (10 or 20 mg ferrous sulfate). In a prospective, unblinded, randomized trial involving 16 healthy, fasting male subjects, Snyder and Clark[71] investigated the effect of administering magnesium hydroxide, in a 5:1 MgOH/Fe ratio, on a supratherapeutic dose of ferrous sulfate, containing a 10-mg/kg dose of elemental iron, ingested 30 minutes later, by measuring serum iron levels at hourly intervals for 6 or 7 hours. The mean peak serum iron level was 300.8 μg/dL in the control group and 272.5 μg/dL in the experimental group, but mean serum iron levels at each time point and peak serum iron levels did not differ significantly between groups. This experiment was subsequently criticized in a letter by Wallace et al.[72] on the basis that iron absorption was not measured for an adequate period to rule out a reduction in iron absorption.

Histamine (H_2) Receptor Antagonists. The inhibition of gastric secretion by the H_2RAs alters the stomach environment for significantly longer periods than simple antacids and can cause malabsorption of dietary iron (and cobalamin), although not necessarily of iron in supplemental form, such as ferrous sulfate. Furthermore, patients with internal bleeding from ulcers demonstrate improved iron status as a result of the intended therapeutic action of the medications. Lastly, evidence from multiple sources indicates that H_2RAs can act as efficient chelators of Fe^{2+} such that coadministration might result in binding and reduced bioavailability of both substances. Macdougall et al.[73] conducted a controlled clinical trial investigating the prevention of bleeding from gastric erosions in patients with fulminant hepatic failure using antacids and H_2 blockers. They found that intragastric pH recordings taken at 2-hour intervals in the treated group could be consistently maintained above 5.0 with the H_2RAs metiamide and cimetidine, as opposed to patients receiving antacids. In the group receiving H_2 blockers only, 1 of 26 patients bled, compared with 13 (54%) of the controls, a highly significant difference. Blood transfusion requirements were significantly less in those treated with H_2RAs. Campbell et al.[61] performed experiments in vitro and in vivo using isolated perfused rat jejunal tissue to examine the binding of iron and cimetidine. They used a dose of cimetidine paralleling a human dose of 300 mg, with the ferrous sulfate doses equivalent to 150- and 300-mg doses. They observed complete inhibition of cimetidine absorption with the higher ferrous sulfate dose, whereas the lower dose of ferrous sulfate caused a 63% reduction in cimetidine absorption. Furthermore, in vitro iron in its ferrous form rapidly oxidized to the ferric form, which then binds to cimetidine. In a prospective, open, multicenter clinical trial, Bianchi et al.[74] studied the effects of concurrent use of famotidine, nizatidine, or ranitidine on response to administration of iron succinyl–protein complex (2400 mg, equivalent to 60 mg iron, twice daily) in a group of patients with iron deficiency or iron deficiency anemia. These researchers observed no significant alteration in iron absorption at the end of 60 days. In this situation the healing of the ulcers, and attendant decreased blood loss, may have improved the iron status of treated individuals.

Partlow and two teams of researchers conducted two studies on the effects of H_2 blockers on absorption of ferrous sulfate. In an in vitro experiment, they found that cimetidine and famotidine bind with iron and that ranitidine did so to a much lesser degree.[75] In a second study, Partlow et al.[76] conducted a series of three experiments investigating the interaction between ferrous sulfate and H_2 blockers and the potential impairment of absorption (of both agents) caused by binding. They observed that the reductions in the AUC and the maximum serum levels (C_{max}) of cimetidine were small (< 16%) when healthy subjects were administered ferrous sulfate, 300 mg, either as a tablet or in solution. Similarly, they observed very small (< 10%) reductions in the AUC and C_{max} of famotidine when 40 mg was administered concurrently with 300 mg ferrous sulfate, as a tablet. Overall, these experiments of short duration have tended to show minimal adverse effects on iron absorption and status as well as on drug availability. Thus, Stockley's review[77] of the subject concludes that evidence is inadequate to confirm a clinically significant reduction of supplemental iron by H_2 blockers. However, extended or repetitive use of H_2RAs may contribute to the occurrence of iron (and/or cobalamin) deficiency anemia.[60]

Despite long-standing knowledge of the intimate and essential role that gastric pH plays in the conversion of ferric to ferrous iron and subsequent bioavailability and absorption, controversy has continued unabated as to whether the suppression of gastric acid is likely to induce a clinically significant effect on iron nutriture and risk of iron depletion and deficiency. In part, this results from the predominant study of ferrous sulfate as a form of medicinal iron rather than a study of food sources, and a methodological emphasis on studies that often last only 1 day, sometimes as long as 2 months, but rarely reflect the extended duration of medication use common in clinical practice. Likewise, the body of available evidence indicates that any reduction in the serum levels of cimetidine and famotidine due to iron are small and clinically irrelevant. Remarkably, given the widespread use of such agents over extended periods, the issue of iron supplementation in individuals receiving acid-suppressive therapies has been the subject of only limited human research.

Reports

An unconfirmed report published by Esposito[78] briefly described a reduction in clinical response to ferrous sulfate (600 mg/day) in three patients taking cimetidine (1 g) and attributed it to the "prolonged periods" of elevated intragastric pH after cimetidine, as previously reported by Macdougall et al.[73] After 2 months' treatment, anemia and altered iron metabolism persisted, even though the ulcers resolved. In a subsequent letter, Rosner[79] noted that the proposed mechanism involved was unconvincing because the iron in ferrous sulfate is Fe^{2+}, not ferric Fe^{2+}, and thus not needing an acidic environment for absorption.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The clinical implications of the interaction between gastric acid–suppressive therapies and iron intake and function operate at two levels. The most immediate and probable pharmacokinetic issue of chelation and decreased absorption and bioavailability affects both iron and pharmaceutical agents. The longer-term and more variable issues of decreased iron

absorption and bioavailability, potentially leading to depletion and deficiency, are subject to more variability in terms of occurrence, severity, and consequences. The former is easily avoided through education regarding the timing of intake. The latter may be offset through iron supplementation or alteration in dietary sources of iron intake, but may only partially address the potential adverse effects of chronic suppression of gastric acid activity.

Stabilization of iron status is central among the many benefits of medical treatment of gastric bleeding, and subsequent enhancement of iron intake may be appropriate in select cases. Anemia due to blood loss is common among the users of antacids and gastric acid–suppressive medications because many have ulcers. Proper medical evaluation of blood and tissue iron status and presence of internal blood loss from GI bleeding are necessary preliminaries to consideration of iron supplementation. Professional supervision and regular monitoring are appropriate once it has been determined that iron administration is appropriate. It is important to inform patients of limitations and risks of acid suppression on an extended basis, including increased susceptibility to *Helicobacter pylori* and other infections, impaired protein digestion and other adverse effects of hypochlorhydria, and disruption of normal GI ecology.[80,86] In clinical practice, complementary approaches for supporting renewal of gastric mucosa typically include deglycyrrhizinated licorice (DGL), zinc carnosine, cabbage leaf (*Brassica oleracea*), cranesbill root (*Geranium maculatum*), marshmallow root (*Althaea officinalis*), and slippery elm bark (*Ulmus rubra*). Ultimately, changes in causative and exacerbating factors underlying dyspepsia and reflux need to be addressed through education about the importance of thorough chewing and relaxing while eating; the inherent risks of excessive portion size and eating late in the evening; the value of paying attention to individual responses to particular foods, food combinations, and eating patterns; potential roles of *H. pylori*; and the influence of stress. Overall, the adverse effect on absorption of iron from food, particularly ferric forms as found in plants, is likely to be greater than on ferrous forms, as found in many iron supplements. Thus, the initial action of these medications in providing a gastric environment more suitable toward healing of ulcerations and resolution of internal bleeding may tend to result in minimal adverse effect on iron status. This situation could, however, change as the continued elevation of gastric pH results in decreased iron absorption from some food sources, particularly ferric iron.

In the event that iron administration is determined to be necessary, a typical adult dose is 100 mg of elemental iron daily. Iron preparations should be taken at least 2 hours before or after antacid medications, particularly cimetidine, sodium bicarbonate, or calcium, to avoid interference with iron absorption (and in some cases drug absorption). In general, gastric acidity is not required for absorption of supplements containing ferrous iron. However, because carbonyl iron requires adequate stomach acid for absorption, concomitant use of PPIs may suppress its absorption. Ferrous fumarate and iron-EDTA may be more bioavailable than ferrous sulfate, particularly in individuals with low (or impaired) gastric acidity. Simultaneous intake of vitamin A and C (> 200 mg/day) may enhance absorption. Increased intake of plant foods and herbs rich in iron and other minerals may be more appropriate than iron supplements for some individuals because of tolerance, compliance, and bioavailability factors. Furthermore, because iron levels in the body are regulated by absorption, rather than by excretion, individuals with low body iron levels, including iron deficiency, can demonstrate increased absorption efficiency, often in the range of 10% to 20%.

Bile Acid Sequestrants

Evidence: Cholestyramine (Locholest, Prevalite, Questran), colestipol (Colestid).
Extrapolated, based on similar properties: Colesevelam (Welchol).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:
2. Probable

Evidence Base:
◉ **Emerging** but
▽ **Mixed**

Effect and Mechanism of Action

When ingested together, iron and cholestyramine or colestipol can bind to form a chelation complex that is poorly absorbable.[63,87] In the process of sequestering intestinal bile acids, these agents may contribute to iron depletion and potential deficiency with long-term use.[88,89] Impaired absorption and resultant decreased bioavailability of the drug could reduce its therapeutic activity.

Research

The body of research regarding the pattern of interactions between iron and bile acid sequestrants is limited, potentially contradictory, and sometimes not focused on key questions of clinical relevance. Using a rat model, Thomas et al.[90] observed that cholestyramine reduced intestinal absorption of a single 100-µg dose of ferrous sulfate by half. Subsequently, this same team extended their research by demonstrating diminished iron stores after prolonged cholestyramine administration.[91] Several years later, in vitro experiments by Leonard et al.[87] demonstrated that cholestyramine and colestipol can both bind iron citrate. The amount of iron citrate bound by colestipol ranged from 95% to 98%. Cholestyramine bound 24% to 97% of the iron citrate in a pH-dependent manner. In another animal study, Watkins et al.[88] found that cholestyramine-fed rats had a net negative balance for calcium and a lower net positive balance for iron, magnesium, and zinc than the controls. These researchers attributed the reported disturbance in iron balance to diminished iron absorption caused by resin binding. Schlierf et al.[92] investigated the availability of minerals and vitamins in young patients with familial hypercholesterolemia administered colestipol over a 5-year period. They reported a lack of significant alterations in plasma levels of iron (as well as of calcium, sodium, parathyroid hormone, and water-soluble and fat-soluble vitamins, except for changes in carotenoid and vitamin E levels paralleling lipoprotein concentrations). The researchers' observation that the treatment was effective in lowering cholesterol levels by 19% indicates that any mutual binding that might have occurred did not significantly impair drug activity.

Notably, no human trials have examined the effect of the observed pharmacokinetic interactions on long-term patterns of depletion in tissue iron stores (as opposed to plasma levels), the influence of intake timing, or the variable responses in

patients with preexisting iron depletion or anemia. In a review of cholesterol-lowering agents, Torkos[89] suggested that an iron deficiency can result from long-term use of colestipol.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing bile acid sequestrants are advised to inform patients of the probable pharmacokinetic interaction between iron and these agents and to recommend separating oral intake by at least 2 hours. Such measures usually allow concurrent use of both agents without interfering with the intended therapeutic activity of either. Despite the lack of solid evidence, many practitioners of nutritional therapeutics recommend regular use of a multivitamin-mineral formula to patients on long-term bile acid sequestrant therapy as a preventive measure in light of the diverse body of evidence indicating significant probability of associated, multiple nutrient deficiency patterns, particularly with fat-soluble vitamins. Such safe and low-cost measures appear judicious pending the emergence of more conclusive evidence based on well-designed, long-term clinical trials.

Bisphosphonates

Alendronate (Fosamax), clodronate (Bonefos, Ostac), etidronate (Didronel), ibandronate (Bondronat, Boniva), pamidronate (Aredia), risedronate (Actonel), tiludronate (Skelid), zoledronic acid (Zometa).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Absorption of bisphosphonates occurs through passive diffusion in the stomach and upper small intestine and is very low and variable (1%-10%). Simultaneous ingestion of cations such as iron (or calcium/magnesium) can result in chelation that significantly reduces absorption and bioavailability of both substances.[93]

Research

Evidence from clinical trials specifically investigating the interaction between iron and bisphosphonates is lacking. Nevertheless, this interaction represents the consensus position within the standard pharmacological literature.[93,94]

No research or case reports were found focusing on potential iron depletion resulting from simultaneous intake of these substances over an extended period.

Clinical Implications and Adaptations

Oral iron preparations need to be taken at least 2 hours away from the bisphosphonate to avoid pharmacokinetic interference. It is generally recommended that oral bisphosphonates be taken with a full glass (6-8 ounces) of plain water on an empty stomach, avoiding the recumbent position for at least 30 minutes to prevent potential severe esophageal irritation associated with incomplete transfer of the tablet to the stomach.

Carbidopa, Levodopa, and Related Antiparkinsonian Medications

Carbidopa (Lodosyn), levodopa (L-dopa; Dopar, Larodopa); combination drugs: levodopa and benserazide (co-beneldopa; Madopar); levodopa and carbidopa (Atamet, Parcopa, Sinemet, Sinemet CR); levodopa, carbidopa, and entacapone (Stalevo).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Iron, especially ferric iron, can bind strongly to carbidopa or levodopa, and the resulting insoluble chelation complexes can significantly reduce absorption and bioavailability of both substances.[49,95-97]

Ferrous iron, such as ferrous sulfate, is formed from ferric iron when it is reduced under the influence of the acidic pH of the GI environment. However, ferrous iron undergoes autooxidation to the ferric form in the presence of methyldopa and levodopa. The formation of these complexes is rapid at high pH (i.e., pH 9), and the rate slows considerably as the pH is lowered (e.g., pH 4). A variety of iron-methyldopa complexes can be formed between pH 4 and 9. Complexation is absent below pH 2. Together these processes can result in both catechol oxidation and production of the toxic hydroxyl radical.[96]

Research

The pioneering research done by Campbell, Hasinoff, and Greene has established the basis for consensus regarding these issues within the pharmacological literature. In a rat model, Campbell et al.[98] observed that ferrous sulfate significantly reduced L-dopa absorption by 22.6% in the duodenum and 23.9% in the jejunum, on average. Furthermore, the authors noted a tendency for ferrous sulfate to cause a greater reduction in L-dopa absorption as the buffer pH increased. They concluded that "the combined results are compatible with the chemical model of increased L-dopa–iron binding as pH increases." Chelation was investigated as a mechanism in iron-induced reduction in levodopa bioavailability in a study involving eight healthy subjects who were administered a single dose of levodopa (250 mg), with and without a single dose of ferrous sulfate (325 mg). When the serum levodopa levels were measured, these researchers observed a 55% decline in peak serum levodopa levels (from 3.6 to 1.6 nmol/L) and a reduction in the AUC by 51% (from 257 to 125 nmol.min/mL). Notably, subjects who had demonstrated the highest peak levels and greatest absorption demonstrated the largest reductions in the presence of ferrous sulfate.[95] Similarly, in a study involving nine patients with Parkinson's disease being treated with Sinemet (100/25 tablet), Campbell et al.[97] found that coadministration of a single dose of ferrous sulfate resulted in a decrease in the AUC of carbidopa by more than 75% and of levodopa by 30%. However, despite an apparently strong relationship observed between reductions in levodopa AUC and reductions in Sinemet efficacy, the average reduction in Sinemet efficacy associated with ferrous sulfate did not achieve

statistical significance. Thus, these authors reported that some patients manifested a worsening of their Parkinson's symptomatology and concluded that the effect on Sinemet availability, when taken concurrently with ferrous sulfate, appears to be clinically significant in some, but not all, patients.[97]

More broadly, an emerging pattern of evidence indicates that chronic iron intake may be contraindicated in patients who would typically be prescribed these medications. Diverse findings suggest that glutathione depletion, oxidative stress, and possibly other factors resulting from iron excess may play a significant role in the pathophysiology of Parkinson's and other neurodegenerative diseases.[42,45,99,100] As noted by Gotz et al.[45]: "Glial iron is mainly stored as ferric iron in ferritin, while neuronal iron is predominantly bound to neuromelanin. Iron overload may induce progressive degeneration of nigrostriatal neurons by facilitating the formation of reactive biological intermediates, including reactive oxygen species, and the formation of cytotoxic protein aggregates." Thus, apart from short-term response in cases involving confirmed comorbid depleted iron stores or iron deficiency anemia, a more appropriate therapeutic strategy might invoke iron chelators in the prevention or treatment of Parkinson's disease in individuals with iron overload, or even with physiological iron stores in the higher ranges of normal.[46,101,102]

Clinical Implications and Adaptations

Despite a relatively consistent body of evidence, the clinical significance of the interaction between iron preparations and levodopa or carbidopa is not fully known. Physicians prescribing levodopa or carbidopa are advised to caution these patients against taking iron supplements outside the context of medical supervision and monitoring. Simultaneous intake can decrease absorption and bioavailability of both substances, which may result in impaired control of Parkinson's symptomatology and interfere with medically appropriate iron support.

In cases where a comprehensive strategy calls for inclusion of both agents as medically necessary and appropriate, intake should be separated by at least 2 hours to avoid impairing their activity. Otherwise, conservative principles of practice suggest that coadministration be discouraged pending substantive research clearly defining mechanisms of action, parameters of effect, and respective risks and benefits.

Cefdinir and Related Cephalosporin Antibiotics

Evidence: Cefdinir (Omnicef).

Extrapolated, based on similar properties: Cefaclor (Ceclor), cefadroxil (Duricef), cefamandole (Mandol), cefazolin (Ancef, Kefzol), cefepime (Maxipime), cefixime (Suprax), cefoperazone (Cefobid), cefotaxime (Claforan), cefotetan (Cefotan), cefoxitin (Mefoxin), cefpodoxime (Vantin), cefprozil (Cefzil), ceftazidime (Ceptaz, Fortaz, Tazicef, Tazidime), ceftibuten (Cedax), ceftizoxime (Cefizox), ceftriaxone (Rocephin), cefuroxime (Ceftin, Kefurox, Zinacef), cephalexin (Keflex, Keftab), cephapirin (Cefadyl), cephradine (Anspor, Velocef); imipenem combination drug: imipenem and cilastatin (Primaxin I.M., Primaxin I.V.); loracarbef (Lorabid); meropenem (Merrem I.V.).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging,** treated as ● **Consensus**

Effect and Mechanism of Action

Supplemental iron salts may diminish absorption and bioavailability of cefdinir and related cephalosporin antibiotics, and vice versa. The mechanism of this interaction has yet to be fully elucidated but is likely caused, at least in part, by binding within the GI tract to form a poorly absorbed, stable chelation complex.[77,103,104]

Research

In a randomized three-way crossover study involving healthy male volunteers, Ueno et al.[103] compared the effects on concentration curve [AUC (0-12)] of cefdinir (200 mg) alone, ingested simultaneously with two tablets of iron ion, and followed 3 hours later by two tablets of iron ion preparation. They observed that the AUC (0-12) of cefdinir with concurrent iron and the AUC (3-12) with delayed iron were both significantly smaller than that with cefdinir alone. However, there were no differences in AUC (0-3) between cefdinir alone and with delayed iron. These researchers interpreted their findings to suggest that the impaired absorption of cefdinir was caused by formation of a chelation complex.

More recently, in an in vitro experiment comparing the effects of calcium polycarbophil granules and iron(III) citrate on cefdinir, Kato et al.[105] found that, in contrast to the calcium compound, "the release of cefdinir from the cellulose membrane in the presence of iron ions was slower than in the absence of iron ions."

Clinical Implications and Adaptations

Physicians prescribing cefdinir or related oral cephalosporin antibiotics are advised to caution these patients against taking iron supplements within 3 hours of the medication. A general caution regarding iron supplementation outside the context of medical supervision and monitoring may also be appropriate with some patients. Simultaneous intake can decrease absorption and bioavailability of the antibiotic, which may impair its antimicrobial activity.

Clinically significant iron depletion caused by simultaneous intake of these substances is improbable over the limited time such medications are typically administered.

Chloramphenicol

Chloramphenicol (Chloromycetin).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable** or **3. Possible**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

At serum levels of 25 µg/mL or more, chloramphenicol can inhibit protein synthesis and cause a reversible bone marrow depression. Although much milder than the irreversible form, in which chloramphenicol can cause aplastic anemia, this more common and possibly unrelated adverse effect can interfere with the activity of iron (or vitamin B_{12}) in the treatment of anemia.

Research and Reports

The adverse effects of chloramphenicol on erythropoiesis and red blood cell (RBC) maturation have been well documented for more than 50 years. In 1954, Rigdon et al.[106] first documented anemia produced by chloramphenicol in the duck. In their study of the effect of chloramphenicol on erythropoiesis, Saidi et al.[107] observed that 10 of 22 patients being treated with iron dextran for iron deficiency anemia failed to demonstrate the expected hematological response when coadministered chloramphenicol. Likewise, four patients being treated with vitamin B_{12} for pernicious anemia were refractory to therapy until chloramphenicol was discontinued. McCurdy[108] reported bone marrow toxicity in series of patients with liver disease after exposure to chloramphenicol. Jiji et al.[109] (1963) published a report of reversible erythropoietic toxicity in healthy volunteers associated with chloramphenicol and its sulfamoyl analog. Two years later, Scott et al.[110] conducted a controlled double-blind study of the hematological toxicity of chloramphenicol and, based on their findings, suggested that drug dosage levels of 25 to 30 mg/kg are usually sufficient for effectively treating infections while minimizing the risk of elevating serum levels to 25 µg/ml or greater, at which bone marrow suppression occurs.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Chloramphenicol may impair the therapeutic effects of iron administration. A decline in the reticulocyte count will indicate inadequate RBC maturation. As recommended by Scott et al.,[110] dosage levels below 25 to 30 mg/kg may be safe and effective, whereas higher doses increase risks of drug-induced adverse effects. Iron coadministration may be judicious in some cases when extended chloramphenicol is anticipated. Consideration of alternative antimicrobials may be warranted in the treatment of individuals diagnosed with depleted iron stores or iron deficiency anemia or otherwise at elevated risk for adverse effects on erythropoiesis and iron function.

Chloramphenicol, although used in some countries such as Mexico, is used extremely rarely in the U.S., and then only in the hands of infectious disease specialists when no alternatives exist. It is not generally available because of the risk of aplastic anemia associated with its use (a life-threatening complication quite different from simple bone marrow suppression).

Chlorhexidine

Chlorhexidine (Chlorohex, Corsodyl, Eludril, Oro-Clense, Peridex, Periochip, Periogard Oral Rinse).

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

Probability: **2. Probable to 1. Certain**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Tooth staining is an adverse effect associated with both chlorhexidine and ingestion of iron in liquid preparations. Concurrent intake may increase the probability and severity of dental staining.

Research

The mechanism and significant probability of this interaction are accepted as consensus within the pharmacological literature, even though the body of direct evidence from controlled clinical trials is relatively limited. In a controlled study using analytical electron microscopy, Warner et al.[111] demonstrated that individuals administered iron immediately after using chlorhexidine developed severe dental staining within 2 weeks. They noted that enhanced levels of sulfur and transition metals, particularly iron, were found in stained regions, whereas unstained regions contained low sulfur and metal levels similar to those treated with water or nonstaining agents.

Clinical Implications and Adaptations

Physicians prescribing chlorhexidine, in liquid dosage forms, are advised to inform patients to prevent this adverse effect by separating intake of iron (as well as sulfur or other transition metals) by at least 1 hour before or 2 hours after using the drug.

Clofibrate

Clofibrate (Atromid-S).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**, treated as ○ **Consensus**

Effect and Mechanism of Action

Clofibrate can bind to iron (and other nutrients) within the GI tract to form a chelation complex that is poorly absorbed and reduces bioavailability of both substances.[112]

Research

Clinical research directly investigating this iron-clofibrate interaction is limited. However, the pharmacological literature accepts this pharmacokinetic interaction as representing a consensus position based on the principles involved and general knowledge of the agents involved.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing clofibrate are advised to inform patients of the probable pharmacokinetic interaction between iron and the medication and to recommend separating oral intake by at least 3 hours. Such measures should allow concurrent use of both agents without interfering with the intended therapeutic activity of either. In general, conservative principles of practice warrant advising patients against taking iron supplements without specific, well-founded therapeutic need and outside the context of medical supervision and monitoring.

Desferoxamine

Desferoxamine (desferrioxamine mesilate, desferoxamine mesylate; Desferal).

Similar properties but evidence lacking for extrapolation: Deferasirox (Exjade).

Interaction Type and Significance

☼ **Prevention or Reduction of Nutrient Adverse Effect**

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

Probability:
1. Certain

Evidence Base:
● **Consensus**

Effect and Mechanism of Action
Desferoxamine mesylate (Desferal) is the chelator of choice for acute iron intoxication and of chronic iron overload caused by transfusion-dependent anemias. It is also used to decrease aluminum accumulation in patients with kidney failure. Desferoxamine can be administered intramuscularly, subcutaneously, or intravenously.

Because desferoxamine is administered to individuals with dangerously high levels of iron, it would be counterproductive to supplement or coadminister iron.

Research
It is self-evident that patients with acute or chronic iron excess being treated with desferoxamine to chelate and remove excess iron should avoid iron supplementation as well as iron-rich foods. Thus, no specific research studies have ever combined desferoxamine with iron coadministration because the interaction is obvious.

Clinical Implications and Adaptations
Chelation with desferoxamine or other agents requires appropriate training and proper monitoring. Assessment of nutrient status is appropriate, and clinical responses will vary accordingly. Iron supplementation would exacerbate the condition of patients prescribed desferoxamine. Thus, iron-containing products of any type are contraindicated in individuals receiving appropriate desferoxamine therapy and specifically need to be avoided during such treatment. Physicians who administer desferoxamine for chelation of heavy metals or other clinical applications routinely supplement their patients with minerals of nutritional importance. Patients undergoing iron removal therapy should be made aware that they should avoid over-the-counter (OTC) multivitamin-mineral preparations that contain iron.

Dimercaprol

Dimercaprol (British antilewisite [BAL], dicaptol, dithioglycerol, sulfactin).
Similar properties but evidence lacking for extrapolation: Other metal chelators, such as DMPS (2,3-dimercapto-1-propanesulfonic acid) or DMSA (2,3-dimercaptosuccinic acid).

Interaction Type and Significance
✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

Probability:
2. Probable

Evidence Base:
● **Consensus**

Effect and Mechanism of Action
Dimercaprol is an effective antidote in arsenic, cadmium, lead, and mercury poisoning and is most efficient if administered intramuscularly immediately after exposure to the metal. Dimercaprol's mechanism of action involves the formation of toxic complexes with iron, cadmium, selenium, and uranium. Nevertheless, dimercaprol cannot be used in poisoning from iron, cadmium, tellurium, selenium, vanadium, or uranium; it is also contraindicated in poisoning from elemental mercury vapor.

Research
Research into this interaction is implicitly contained within the clinical trials, case reports, and clinical experience of the therapeutic application of dimercaprol.

Clinical Implications and Adaptations
Physicians administering dimercaprol need to avoid iron administration out of sequence. Iron therapy is often administered 24 hours or more after the last dose of dimercaprol. However, the concomitant intake of iron and dimercaprol can result in serious renal injury. Warnings to patients to avoid iron supplements would seem reasonable but are usually unnecessary because this medication is typically administered in emergency or inpatient settings.

EDTA

EDTA (Ethylenediaminetetraacetic acid).

Interaction Type and Significance
☼ **Prevention or Reduction of Nutrient Adverse Effect**
◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**
✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

Probability:
1. Certain

Evidence Base:
● **Consensus**

Effect and Mechanism of Action
EDTA binds to iron (and other minerals) and thereby increases iron excretion. EDTA may be used to treat iron overload, although it is much less efficient than desferoxamine. Conversely, chelation therapy with EDTA could induce or exacerbate depleted iron stores if compensatory nutrient augmentation is appropriate but not provided.

Research
The chelation function of EDTA is central to its primary pharmacological action in therapeutic application.

Conversely, iron chelates, such as ferric EDTA, sodium iron EDTA [NaFe(III)EDTA], and ferrous bisglycinate, have been proposed as promising alternatives to iron salts for food fortification based on recent studies involving healthy and at-risk infants and children.[113,114] Continued research is warranted.

Clinical Implications and Adaptations
Chelation with EDTA or other agents requires appropriate training and proper monitoring. Assessment of iron status is appropriate, and clinical responses will vary accordingly. When properly administered, EDTA chelation is considered unlikely to result in adverse reactions caused by iron depletion. Physicians who administer EDTA for chelation of heavy metals or other clinical applications routinely coadminister minerals of nutritional importance as part of a strategic therapeutic protocol.

Erythropoiesis-Stimulating Agents

Epoetin alpha (EPO, epoetin alfa, recombinant erythropoietin; Epogen, Eprex, Procrit), epoetin beta (NeoRecormon), darbepoetin alpha (darbepoetin alfa; Aranesp).
See also Vitamin C monograph.

Interaction Type and Significance

⊕⊕ Beneficial or Supportive Interaction, with Professional Management

⊕✗ Bimodal or Variable Interaction, with Professional Management

✗✗ Minimal to Mild Adverse Interaction—Vigilance Necessary

✗✗✗ Potentially Harmful or Serious Adverse Interaction—Avoid

Probability: 2. Probable

Evidence Base: ◉ Emerging, ▽ Mixed

Effect and Mechanism of Action

Erythropoietin is an endogenous peptide, produced primarily by the kidneys, which drives erythropoiesis in the bone marrow. It became available as a recombinant peptide hormone for therapeutic use in the 1980s.

Approximately 50% of oncology patients develop anemia, with that incidence rising dramatically in patients with more advanced cancer or in those receiving chemotherapy and/or radiation therapy. Within conventional oncology, *recombinant human erythropoietin* (rHuEpo) represents the standard of care in managing cancer therapy-related anemia and fatigue, increasing hemoglobin levels, reducing transfusion need, and improving patient quality of life. Likewise, rHuEpo may correct anemia in chronic renal failure (CRF) patients, in iron-deficient erythropoiesis associated with the anemia of chronic disease (ACD), and in primary bone marrow dysfunction states, such as myelodysplastic syndrome. By stimulating erythropoiesis, erythropoietin may increase synthesis of RBCs, thereby increasing metabolic need for iron. Iron coadministration, intravenous/parenteral or oral, could improve the response to erythropoietin or rHuEpo in cases of iron-deficient erythropoiesis by delivering adequate iron to the bone marrow.

Research

Since the late 1980s, rHuEpo has provided a safe and effective option for treating cancer-related anemia and fatigue. Recent research confirmed that epoetin beta, 30,000 IU once weekly, is equally effective as the conventional 10,000 IU three times weekly in alleviating cancer-related anemia.[115] Nevertheless, erythropoietin therapy exhibits variable response rates, and 30% to 50% of patients did not respond adequately to treatment in some trials. True iron deficiency is the most common cause of an inadequate response to rHuEpo in CRF patients. However, in oncology patients, this failure may be caused by factors related to the underlying disease, adverse effects of chemotherapy or radiotherapy, functional iron deficiency, or some combination.[116,117] Thus, in cases of functional iron deficiency, patients may not respond to rHuEpo when iron availability is inadequate to the demands of erythropoietin-induced erythropoiesis, despite the presence of adequate bone marrow iron stores.

Since the emergence of rHuEpo as a standard treatment, concomitant iron has often been proposed as an important therapeutic option in optimizing the response of cancer-related anemia to rHuEpo.[118] Guidelines published by the American Society of Clinical Oncology and American Society of Hematology recommend iron repletion in patients receiving rHuEpo when functional iron deficiency is present, based on indirect evidence and biological inferences.[117] A growing body of literature regarding chronic renal failure patients has shown that iron coadministration can correct functional iron deficiency and may improve erythropoietin response, with IV iron doing so more effectively than oral iron.

Markowitz et al.[119] conducted a double-blind, placebo-controlled trial to evaluate the effectiveness of oral iron therapy in 49 hemodialysis patients receiving rHuEpo. They divided the subjects into two groups, based on adequate or deficient iron stores, and treated them for 3 months with 150 mg elemental iron (polysaccharide complex) or placebo, twice daily. Over 5 months they observed that iron-replete patients, in both oral iron and placebo subgroups, demonstrated decreasing iron stores; that is, oral iron failed to maintain their iron stores. Furthermore, compared to iron-replete patients, iron-deficient patients had a significantly greater dropout rate because of adverse effects, even though responses to the side effect questionnaire were equivalent, suggesting poor medication compliance. Beguin[116] found that oral iron is largely ineffective in the treatment of anemia in chronic diseases other than cancer, mainly because of the development of iron deficiency, which significantly limits the efficacy of rHuEpo therapy.

Oral iron products in patients with ESRD have been largely abandoned, and the safety of IV iron preparations has improved with the introduction of new-generation compounds that have significantly reduced incidence of allergenicity. Since its approval, sodium ferric gluconate complex (SFGC) has largely displaced iron dextran as the primary form of IV iron, which had been associated with significant adverse reactions, including anaphylaxis and death. Adverse reactions to SFGC are uncommon in hemodialysis patients, including both iron dextran–sensitive and dextran-tolerant patients.[120] These findings indicate that dextran, rather than iron, is the cause of most reactions to iron dextran administration.

Iron deficiency is the most common cause of suboptimal response to rHuEpo in chronic hemodialysis patients. Intravenous iron can improve hemoglobin response, help maintain adequate iron stores, and decrease erythropoietin dosage requirements in hemodialysis patients and patients with anemia of kidney disease. In 1997, Kooistra et al.[121] investigated the effects of iron availability, inflammation, and aluminum on iron absorption in 19 chronic hemodialysis patients on maintenance erythropoietin (rHuEpo) therapy. They concluded that iron absorption is decreased in hemodialysis patients with elevated C-reactive protein (CRP) values and higher levels of aluminum ingestion. Iron absorption correlated significantly with transferrin saturation and CRP in the iron-deficient group, and with serum ferritin in the iron-replete group. Auerbach et al.[122] conducted a randomized trial involving 43 hemodialysis patients receiving rHuEpo (epoietin alpha) to investigate three iron dextran infusion methods for anemia. They reported no significant differences in efficacy and safety (as measured by time to the maximum hemoglobin and adverse reactions) when they compared subjects who received IV iron dextran as a total-dose infusion, 500-mg infusion to total dose, or 100-mg bolus to total dose, in each case during the dialysis procedure.

In a trial involving 24 patients of an outpatient dialysis center, Vankova et al.[123] reported significant improvements obtained by tracking hematocrit, transferrin saturation, and ferritin levels and adjusting iron and rHuEpo dosage accordingly. In 23 patients (96%), transferrin saturation levels were within the recommended range after treatment. Hematocrit increased from 27.7% to 35.7%, with the recommended value of 33% being achieved in 18 patients. Overall, the weekly dose of rHuEPO fell from 3958 IU to 2042 IU, and the average dose of iron administered was 157 mg per week. Similarly, Chang et al.[124] conducted a 12-month IV iron substitution trial in 149 iron-replete chronic hemodialysis patients receiving subcutaneous rHuEpo therapy. They maintained the available

iron pool with 100 mg iron every 2 weeks or 1 month, depending on serum ferritin and transferrin saturation levels, with the rHuEpo dosage titrated depending on hematocrit levels. After 12 months these researchers reported increases in the hematocrit, serum ferritin, and transferrin saturation along with a 25% reduction in rHuEpo requirement. The authors concluded that maintaining high levels of serum ferritin and transferrin saturation could further reduce the requirement of erythropoietin in chronic hemodialysis patients, but cautioned that "the long-term effect of iron overloading... must be further evaluated in contrast to the economic saving."[124]

However, oral heme iron may provide an effective option for iron therapy in hemodialysis patients because it is absorbed by patients with high ferritin levels, it has fewer adverse effects, and its absorption is stimulated by erythropoietin administration. In an open, 6-month, prospective evaluation of heme iron in 37 hemodialysis patients who had been on maintenance IV iron therapy, Nissenson et al.[125] discontinued the IV iron and replaced it with oral heme iron. Among the 28 subjects who completed the study, the authors observed an initial slight reduction in average transferrin saturation, which subsequently reversed, and a significant reduction in average serum ferritin level was seen at months 4 through 6. No significant changes were seen in average transferrin saturation or hematocrit. The authors concluded that heme iron polypeptide successfully replaced IV iron therapy in a majority of hemodialysis patients during the 6-month study period, maintained target hematocrits with no concomitant use of IV iron, and thus was associated with a significant increase in rHuEpo efficiency.

Ongoing research is examining the role of concomitant IV iron during epoetin therapy with the aim of further improving the effectiveness of epoietins in anemia treatment. A study published in 2004 was the first controlled trial confirming that iron should be coadministered intravenously rather then orally in cancer patients with chemotherapy-related anemia. In a prospective, multicenter, open-label, randomized trial involving 157 patients, Auerbach et al.[126] found that IV iron optimizes the response to rHuEpo in cancer patients with chemotherapy-related anemia. In addition to rHuEpo, 40,000 U subcutaneously once weekly, subjects received (1) no iron; (2) 325 mg iron orally twice daily; (3) iron dextran, repeated 100-mg IV bolus; or (4) iron dextran total-dose infusion (TDI). They reported that subjects in all four groups showed hemoglobin (Hb) increases from baseline with mean Hb increases for both IV iron groups were greater than for no-iron and oral iron groups. Patients in both groups receiving IV iron demonstrated higher hematopoietic responses (68%) than did those in the groups receiving no iron (25%) and oral iron (36%). Furthermore, subjects in the IV iron group showed increases in energy, activity, and overall quality of life from baseline, compared with a decrease in energy and activity for the no-iron group and no change in activity or overall quality of life for the oral iron group. The authors concluded that rHuEpo increases Hb levels and improves quality of life in patients with chemotherapy-related anemia, and that coadministration of IV iron significantly increased the magnitude of improvement for both outcomes. Patients were not followed long term to determine whether the therapy had any positive or negative impact on cancer specific survival. In a letter, Pedrazzoli et al.[127] responded with a cautionary approach: "Because of absence of iron stores, in this subset of patients, it is clinically cautious to postpone treatment with erythropoietic agents until iron stores are replenished or to treat iron deficiency aggressively along with rHuEpo therapy." In contrast, in a randomized, double-blind, placebo-controlled trial involving 351 head and neck cancer patients with anemia undergoing radiotherapy, Henke et al.[128] found that epoetin beta corrected anemia but did not improve cancer control or survival, and in fact, locoregional progression-free survival was poorer with epoetin beta than with placebo. Moreover, whether concomitant iron can increase the proportion of patients without iron deficiency responding to erythropoietic agents remains the subject of ongoing controversy and an area in need of further elucidation within the field of rHuEpo therapy for anemia of cancer.

Anemia of chronic disease (ACD) is a frequent complication of chronic inflammation in rheumatoid arthritis and other conditions. The cytokine interleukin-6 (IL-6) mediates hypoferremia (anemia) of inflammation by inducing the synthesis of the iron-regulatory hormone hepcidin.[129,130] Arndt et al.[131] investigated the concomitant use of rHuEpo and parenteral iron to correct iron-deficient erythropoiesis (IDE) in patients diagnosed with anemia of chronic disease. They treated 30 rheumatoid arthritis patients with ACD using subcutaneous rHuEpo, 150 IU/kg twice weekly. Intravenous iron (200 mg iron sucrose once weekly) was coadministered in cases of IDE, as defined by the presence of two of three criteria: saturation of transferrin 15% or less, hypochromic erythrocytes 10% or more, and serum ferritin concentration 50 µg/L or less. The authors reported that all 28 subjects who completed the trial met the treatment goal of successful correction of anemia, with an increase of the median Hb concentration from 10.3 to 13.3 g/dL, and concluded that such coadministration of erythropoietin and iron was safe, effective, and well tolerated in all patients.

Nutritional Therapeutics, Clinical Concerns and Adaptations

Physicians administering erythropoietin are advised to exercise caution in the coadministration of iron, especially IV iron within the context of oncological care. Combination therapy using erythropoietin and iron is controversial and awaits greater evolution of clinical research, particularly specificity to individuals, conditions, and stages of treatment.[116] The erythropoietic response is a tactical element within the broader therapeutic strategy and, although evoking apparent short-term benefits using narrow parameters of hematological response, may be irrelevant or deleterious, even counterproductive, to achieving the desired clinical outcome, such as the strategic goal of eliminating cancer.[132] Thus, this intervention could be beneficial or adverse, depending on the particulars of the case.

Most anemia is cancer patients is the "anemia of chronic inflammation," which although sometimes similar in presentation to iron deficiency, is part of a protective response, similar to that in acute infection; the body "locks down" iron to keep it out of circulation to counter the proliferative process, because most malignant cells and pathogenic bacteria require iron for rapid proliferation. Erythropoietin (EPO) is most appropriate in anemic cancer patients, and then only after assessing the endogenous EPO level and determining that it is not already extremely elevated. Iron is coadministered most safely and effectively only when there has been no or only minor response to initial EPO therapy. It is essential to monitor iron status and to address either true or functional iron deficiency before and during rHuEpo therapy to optimize the effect of rHuEpo in cancer patients. It must also be kept in mind that oncology patients with limited iron stores may become iron deficient as a result of erythropoiesis stimulated by EPO therapy, which then limits further response unless iron is supplied. The IV route shows significantly greater efficacy than the oral route with inorganic iron preparations. Oral

administration of heme iron should also be investigated in this population.

Coadministration of ascorbic acid may also be indicated in certain cases, especially involving resistance to EPO in hemodialysis patients with functional iron deficiency.

Fluoroquinolone (4-Quinolone) Antibiotics

Evidence: Ciprofloxacin (Ciloxan, Cipro), gatifloxacin (Tequin), levofloxacin (Levaquin), norfloxacin (Noroxin), ofloxacin (Floxin, Ocuflox), spartfloxacin (Zagam).
Minimally affected: Lomefloxacin (Maxaquin).
Extrapolated, based on similar properties: Cinoxacin (Cinobac, Pulvules), enoxacin (Penetrex), lomefloxacin (Maxaquin), moxifloxacin (Avelox), nalidixic acid (Neggram), trovafloxacin (alatrofloxacin; Trovan).
Related but evidence against extrapolation: Fleroxacin.
Nutrient form with similar properties but evidence indicating no or reduced interaction effects: Iron-ovotransferrin.

Effect and Mechanism of Action

Iron and the 3-carbonyl and 4-oxo functional groups on quinolone antibiotics can bind within the GI tract to form a poorly absorbed, stable chelation complex, for example, a ferric ion–ciprofloxacin complex. A similar pharmacokinetic interaction can also occur with other divalent metal cations, such as aluminum, calcium, copper, magnesium, manganese, and zinc, as well as mineral-based antacids.[49,133-141] This binding process can interfere to varying degrees with the absorption, bioavailability, and activity of both the antimicrobials in this class and the orally administered iron.

In contrast to most forms of iron, iron-ovotransferrin can combine directly with the transferrin receptors of intestinal cells, and thus may release only minimal amounts of elemental iron into the gut to bind with the quinolones.[142,143]

However, an experiment using a rat model to examine the pharmacokinetics and pharmacodynamics aspects of the interaction between oral ferrous sulfate and IV ciprofloxacin suggested that the observed effects may only partially be attributable to direct physical interaction in the GI tract.[144]

Research

In vitro experiments first demonstrated the pattern of interaction between quinolones and metals in an aqueous medium and the resultant effects on antimicrobial activity. Subsequently, changes in oral bioavailability and alterations in therapeutic efficacy have been the focus of many previous interaction studies involving metal cations and quinolones. Thus, through multiple lines of research, the ability of multivalent cations to reduce the absorption and serum levels of oral quinolone antibiotics is well established.

Iron salts, particularly ferrous fumarate, gluconate, and sulfate, can reduce the absorption of ciprofloxacin, gatifloxacin, levofloxacin, norfloxacin, ofloxacin, and spartfloxacin from the GI tract to a degree that can interfere with therapeutic activity. In contrast, iron only minimally affects lomefloxacin, and separation of intake renders insignificant any interaction between gemifloxacin and ferrous sulfate. Iron does not appear to interact significantly with fleroxacin. Notably, iron-ovotransferrin appears to exert no adverse effect on quinolone absorption because of its direct binding to intestinal transferrin receptors. Thus, in his review of the various interactions between iron and members of this drug class, Stockley[77] summarizes the body of evidence as revealing a pattern of descending order in the degree to which the serum levels of the various quinolone antibiotics can become subtherapeutic and thus subject to clinically significant interaction, as follows:

Norfloxacin > levofloxacin > ciprofloxacin > gatifloxacin > ofloxacin > sparfloxacin > lomefloxacin.

Ciprofloxacin. Many studies have confirmed that compounds containing elemental iron can greatly decrease absorption of ciprofloxacin, with demonstrated reductions in the AUC and C_{max} of 30% to 90%. Several studies have documented this effect with ferrous sulfate.[135,138,145] For example, in a four-way crossover trial with 12 healthy volunteers, Polk et al.[133] (1989) observed a clinically significant reduction in the absorption of oral doses of ciprofloxacin (500 mg) when administered with ferrous sulfate (325 mg orally three times daily) or a multivitamin-mineral formulation containing zinc. Notably, peak concentrations of ciprofloxacin with ferrous sulfate regimen were below the minimum inhibitory concentration (MIC) for 90% of strains of many organisms normally considered susceptible to the antimicrobial activity of ciprofloxacin. Also in 1989, Lode et al.[146] demonstrated a pharmacokinetic interaction between oral ciprofloxacin/ofloxacin and iron glycine sulfate. A year later, Brouwers et al.[147] published research showing decreased ciprofloxacin absorption with concomitant administration of ferrous fumarate. Kara et al.[135] investigated clinical and chemical interactions between ciprofloxacin and iron preparations and found impairment of absorption with ferrous gluconate and a multimineral preparation containing iron, magnesium, zinc, calcium, copper, and manganese (Centrum Forte). They reported that when ferrous ion was mixed with ciprofloxacin, rapid spectral changes occurred in a manner consistent with oxidation of the ferrous form of iron to its ferric form, followed by rapid formation of a Fe^{3+}-ciprofloxacin complex. Ciprofloxacin seems to bind to ferric ion in a ratio of 3:1 by interacting with the 4-keto and 3-carboxyl groups on ciprofloxacin. These authors concluded that the formation of a ferric ion–ciprofloxacin complex was most likely responsible for the reduction in ciprofloxacin bioavailability in the presence of iron. In contrast, iron-ovotransferrin, a novel iron formulation in which iron ions are bound to ovotransferrin, has been found to have no significant effect on the absorption of ciprofloxacin from the GI tract and thus only minimally effects the drug's margin of efficacy.[142,143]

However, based on findings from an experiment using a rat model to examine the pharmacokinetics and pharmacodynamics of the interaction between oral ferrous sulfate and IV ciprofloxacin, Wong et al.[144] suggested that the observed effects may only partially be attributable to direct physical interaction in the GI tract. Further research is warranted to investigate the concern that oral iron might interfere even with parenteral fluoroquinolones.

Fleroxacin. In a study involving 12 volunteers, Sörgel et al.[148] observed that ferrous sulfate (equivalent to 100 mg elemental iron) exerted no significant effect on the pharmacokinetics of fleroxacin.

Gatifloxacin. Shiba et al.[149] conducted a study of gatifloxacin pharmacokinetics involving six healthy volunteers that showed coadministration of ferrous sulfate (160 mg) and gatifloxacin (200 mg) produced a 49% decrease in the C_{max} and 29% decrease in the AUC of gatifloxacin.

Gemifloxacin. Allen et al.[150] observed no significant alterations in pharmacokinetics and bioavailability when they administered gemifloxacin (320 mg) to 27 healthy volunteers either 2 hours after or 3 hours before ferrous sulfate (325 mg).

Levofloxacin. Shiba et al.[151] reported that ferrous sulfate, when taken concurrently, inhibited levofloxacin absorption and reduced bioavailability by 79%.

Lomefloxacin. Lehto and Kivisto[152] demonstrated that coadministration of ferrous sulfate (equivalent to 100 mg elemental iron) with lomefloxacin (400 mg) reduced the lomefloxacin C_{max} by approximately 28% and the AUC by approximately 14%.

Moxifloxacin. In their review of moxifloxacin, Balfour and Wiseman[140] concluded that bioavailability of the medication is substantially reduced by coadministration with an iron preparation or antacid.

Norfloxacin. In a single-dose study assessing the pharmacokinetic interactions of norfloxacin with iron and metallic agents, Okhamafe et al.[134] reported a 97% reduction in bioavailability with iron. Campbell et al.[153] found that ferrous sulfate reduced the urinary recovery of norfloxacin by 55%; similar effects occurred with zinc sulfate. Subsequently, in eight normal subjects, Lehto et al.[138] observed that ferrous sulfate reduced the AUC of a single 400-mg dose of norfloxacin by 73% and the C_{max} by 75%. Similarly, Kanemitsu et al.[154,155] noted a 51% reduction in the norfloxacin AUC with ferrous sulfate.

Ofloxacin. In a study involving 12 healthy subjects, Lode et al.[146] found that an iron-glycine-sulfate complex (containing 200 mg elemental iron) reduced the bioavailability of ofloxacin (400 mg) by 36%. However, in an experiment with nine healthy volunteers, Martinez Cabarga et al.[156] observed only an 11% decrease in GI absorption of ofloxacin (200 mg) with coadministration of ferrous sulfate (1050 mg). In a 1994 study with eight healthy subjects, Lehto et al.[138] observed that coadministration of ferrous sulfate (100 mg elemental iron) reduced the AUC and C_{max} after a single dose of ofloxacin (400 mg) by 25% and 36%, respectively.

Sparfloxacin. In a single-dose study assessing the effect of ferrous sulfate on the pharmacokinetics of sparfloxacin, Kanemitsu et al.[154,155] reported that 525 mg ferrous sulfate (170 mg elemental iron) reduced the AUC of sparfloxacin (200 mg) by 27% in six subjects.

Iron Depletion. Iron depletion resulting from chelation by this class of medications has not been studied per se. Although plausible, such an adverse effect on iron status is highly improbable, given the normal physiological controls on iron levels, variable absorption rates, and the limited duration of standard fluoroquinolone antibiotic use. Long-term quinolone therapy and simultaneous oral iron intake in the face of iron deficiency could theoretically contribute to lack of tissue repletion. It is not clear whether or not long-term oral fluoroquinolone antibiotic therapy might cause iron deficiency in certain persons, such as menstruating women, by preventing dietary iron absorption.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The reduction of fluoroquinolone activity by concomitant iron is the primary established interaction between these two groups of agents; the potential depletion of iron through the same mechanisms is plausible, but it is generally improbable in standard clinical usage. Both directions of interaction and decreased bioavailability can be adequately avoided through proper patient education and dose timing.

Physicians treating patients for serious infections with quinolone antibiotics should advise that they refrain from ingesting iron supplements or using multivitamin-mineral formulations containing iron or other divalent mineral cations during the course of therapy, to avoid interfering with the absorption and thus the antimicrobial action of the medication.

Iron intake can usually be temporarily halted in most patients but can be continued with separation of intake timing in those for whom iron repletion has been confirmed as necessary to their therapeutic strategy. If this is not possible, administration of the medication 2 hours before or 6 hours after ingestion of an oral iron preparation is suggested and can effectively minimize risk of an adverse interaction (i.e., antibiotic malabsorption). This recommendation also applies to intake of iron-rich or iron-fortified foods. Monitor for decreased therapeutic effects of oral quinolones if inadvertently administered simultaneously with oral iron supplements. A special iron formulation, in which iron ions are bound to ovotransferrin, is less likely than the usual iron salts to reduce drug absorption.

Hyoscyamine

Hyoscyamine (Anaspaz, A-Spas S/L, Cystospaz, Cystospaz-M, Donnamar, ED-SPAZ, Gastrosed, Levbid, Levsin, Levsinex, Levsin/SL).

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:	Evidence Base:
4. Plausible	○ **Preliminary**

Effect and Mechanism of Action

Hyoscyamine impairs absorption of ferrous citrate. The mechanism of this interaction has not been fully elucidated but may be caused by the drug's anticholinergic activity.

Research

Orrego-Matte et al.[157] found that absorption of ferrous sulfate, which is usually well absorbed, was impaired in individuals administered hyoscyamine.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing hyoscyamine are advised to ask patients if they are taking supplements containing iron. Concomitant intake could limit the therapeutic activity and clinical efficacy of either agent. Long-term coadministration could potentially contribute to depletion of iron stores, particularly in individuals presenting with or susceptible to iron deficiency. If iron administration is clinically warranted, separation of intake is appropriate to avoid interference with absorption.

Indomethacin and Related Nonsteroidal Anti-Inflammatory Drugs (NSAIDS)

Evidence: Indomethacin (indometacin; Indocin, Indocin-SR). Extrapolated, based on similar properties:

COX-1 inhibitors: Diclofenac (Cataflam, Voltaren); combination drug: diclofenac and misoprostol (Arthrotec); diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), flurbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen); combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen); ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Aleve, Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).

COX-2 inhibitor: Celecoxib (Celebrex).

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

The activity of NSAIDs in inhibiting the effects of cyclooxygenase (COX) extends beyond those functions involved in inflammatory responses. In the stomach the enzyme's products build bicarbonate and mucus buffers against stomach acidity, without which the risk of ulceration can increase 20-fold. In general, NSAIDs can damage the epithelium of the stomach as well as the small and large intestines, causing ulceration, increased small intestine permeability, chronic bleeding, and eventually iron deficiency.[158-160] Oral indomethacin is one of the most damaging NSAIDs in this regard. Iron coadministration may provide a means of countering the nutrient depletion effect of such medications.

Indomethacin's primary action is prostaglandin inhibition through the COX pathway. Indomethacin causes anemia by two possible mechanisms: (1) peptic ulceration or GI bleeding and (2) interference with normal iron metabolism and erythropoiesis. Curiously, edible black ink derived from black iron oxide is often used as a nonmedicinal ingredient in indomethacin capsules.

Both NSAIDs and iron can cause GI irritation; thus, concomitant use represents a potential additive adverse effect. Excessive iron intake can also contribute to inflammatory processes.

Research

Iron loss resulting from GI bleeding is well established as an adverse effect associated with indomethacin or other NSAIDs. Additionally, according to a nested case-control analysis of multiple linked health care databases conducted by Canadian researchers, patients taking warfarin at the same time as selective COX-2 inhibitors or nonselective NSAIDs have an increased risk of hospitalization for upper GI hemorrhage.[161]

Animal research indicates that prostaglandins are necessary for normal iron metabolism and for erythropoiesis.[162,163] Notably, indomethacin has also been associated with aplastic anemia.[164-166]

Although widely discussed as if evidence based, the specific use of iron coadministration to reverse this depletion pattern has not been the subject of significant human research, as indicated by a search of the scientific literature.

Lactoferrin is a glycoprotein present in human breast milk and other body fluids and is available as a supplement derived from bovine whey protein, which has been shown to act as an antioxidant, anti-inflammatory, and bactericidal agent as well as having an immunomodulatory effect. In a study presented at the Digestive Disease Week meeting on May 20, 2001, Dr. Troost observed the concomitant administration of this form of iron with indomethacin to iron-deficient women resulted in an additional increase in intestinal permeability. Furthermore, he reported: "When iron is bound to lactoferrin, it is not able to catalyze free radical formation."[167] In related research, Troost et al.[168] conducted a randomized crossover dietary intervention involving 15 healthy volunteers to determine whether administration of recombinant human lactoferrin (rhLF) inhibits NSAID-induced gastroenteropathy in vivo as a model for disorders associated with increased permeability of the stomach and small intestine. They demonstrated that intestinal permeability after the administration of indomethacin and lactoferrin was significantly reduced compared with the permeability observed after ingestion of indomethacin and placebo, underscoring rhLF's potential as a GI-protective agent; in contrast, gastroduodenal permeability did not differ between the two interventions. These researchers concluded that "oral recombinant human lactoferrin supplementation during a short-term indomethacin challenge reduced the NSAID-mediated increase in small intestinal permeability and hence may provide a nutritional tool in the treatment of hyperpermeability-associated disorders." The authors noted that the protective mechanism of lactoferrin is still undetermined, but it may be related to its ability to bind strongly to iron, thus acting as an antioxidant.[168]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing NSAIDs for extended use are advised to monitor for blood loss and iron depletion; frank questioning of patients regarding self-medication is also necessary. In cases where both iron and indomethacin (or another NSAID) are required, based on established iron deficiency or tissue depletion, the patient should be advised to take the substances with food to reduce stomach irritation and bleeding risk. In cases of existing GI irritation, the use of iron-rich foods and herbs may be more efficacious and better tolerated. Investigation to identify and therapeutic intervention to address the causes of inflammatory processes are fundamental in individuals with chronic inflammation.

Interferon Alpha

Interferon alpha (Alferon N, Intron A, Roferon-A); combination drug: interferon alfa-2b and ribavirin (Rebetron).

Interaction Type and Significance

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Pathogenic microorganisms such as the hepatitis C virus require iron to replicate. Reduction of iron levels, particularly in the liver, appears to inhibit viral replication and increase efficacy of interferon therapy, especially within the context of complementary measures, such as adding cytokines and antivirals. Iron supplementation would counter this therapeutic approach: moreover, reducing iron intake is consistent with the therapeutic strategy.

Research

Hepatic iron concentration has consistently been observed as being directly correlated with the response to interferon therapy in patients with chronic hepatitis C infection. In 1981, Blumberg et al.[169] first reported that patients with hepatitis B viral infection who had higher serum iron or ferritin levels were more likely to develop chronic infections than those with lower levels, who more often experienced spontaneous resolution of their infections. Patients with chronic hepatitis C have high frequencies of elevated levels of serum ferritin, iron, and transferrin saturation, and these higher levels are generally associated with decreased likelihood of response to interferon therapy. Notably, complete responders to interferon, on average, demonstrate lower hepatic iron concentrations than do noncomplete responders.[170,171] Hayashi et al.[172] reported that bloodletting through repeated venesection reduced iron levels to a degree sufficient to cause significant improvement in serum alanine transaminase (ALT) levels in subjects with chronic active hepatitis C and excess hepatic iron. In two studies, research teams led by Fong[173] (1998) and Fontana[174] (2000) observed that iron reduction through phlebotomy, combined with interferon alpha, reduces liver inflammation, but not fibrosis. Although not statistically significant, their findings indicate that this combination appears to reduce the viral load and may improve sustained response. Notably, ribavirin, which tends to cause anemia (via direct bone marrow suppression), was not part of either treatment protocol being investigated.

In a multicenter, prospective, randomized, controlled trial involving 96 patients with chronic hepatitis C who have previously not responded to interferon, Di Bisceglie et al.[175] compared iron reduction by phlebotomy with iron reduction followed by re-treatment with interferon. They concluded that, "although prior phlebotomy therapy does not improve the rate of sustained response to interferon retreatment, it does result in less liver injury manifested by a decrease in serum transaminase activity and a slight improvement in liver histopathology." In the first randomized, controlled study on the effect of phlebotomy before long-term and high-dose interferon therapy in naive patients with hepatitis C virus–related chronic liver disease, Fargion et al.[176] assessed the outcomes of 114 subjects who were randomized to receive interferon alone or interferon preceded by phlebotomy. In both groups, interferon was given at a dose of 6 mU three times a week for 4 months, followed by 3 mU three times a week for 8 months. The virological sustained response rate in the interferon-only group was 15.8% compared with 28.1% in the iron-depletion group. Patients who underwent phlebotomy tended to respond better to interferon therapy than patients without iron reduction. The difference in sustained response rates between the treatment groups was almost significant for subjects with hepatic iron concentrations no greater than 1100 μg/g dry weight. In contrast to earlier studies indicating that iron removal can improve the histological and virological response to short-term interferon therapy, this latest research demonstrates an improved sustained response when longer courses and higher doses of interferon therapy are administered.

Although the body of literature on use of iron reduction therapy together with interferon suggests the possibility of an effective cure rate of about 75% to 80%, which might be enhanced through the addition of cytokines and antivirals such as ribavirin, trials are evolving from being inconclusive toward consensus.

In India, phlebotomy is not socially acceptable as a means of reducing iron overload to improve the efficacy of interferon therapy. Tandon et al.[177] investigated the efficacy of an indigenous, low-iron, vegetarian diet in reducing serum Fe levels in 19 patients with hepatitis B–related and hepatitis C–related chronic liver disease. One group of 10 subjects had normal (< 25 μmol/l) baseline serum Fe levels, whereas another nine had high (> 25 μmol/l) serum Fe levels. All the subjects were advised to eat a low-Fe rice-based diet, which decreased the daily Fe intake by approximately 50%. All patients complied with the dietary regimen, and at 4 months, significant reductions from baseline were seen in serum Fe and transferrin saturation index (TSI) in both groups, although earlier in those subjects with the higher initial serum Fe levels. Serum ferritin levels, however, were reduced only in the group with lower initial serum Fe levels and not in those with higher initial serum Fe levels. The ALT levels were reduced significantly in both groups. These authors concluded that a low-iron diet results in significant reductions in serum Fe and TSI levels, regardless of baseline Fe levels, and recommended that such a diet should be evaluated to improve the efficacy of interferon therapy in patients with hepatitis B/C–related chronic liver disease.

In a potentially related area, in a pilot study involving 11 patients with chronic hepatitis C virus (HCV) infection, Tanaka et al.[178] found that bovine lactoferrin, 1.8 to 3.6 g daily for 8 weeks, suppressed ALT levels and viral load (as indicated by HCV RNA concentrations) in three of four patients with low pretreatment serum concentrations of HCV RNA. However, seven patients with high pretreatment concentrations showed no significant changes in these indices. The authors suggested that bovine lactoferrin, a subfraction of milk whey protein belonging to the iron transporter family, could be used with any combination of antiviral therapies, including interferon plus ribavirin, without adverse effects.

Clinical Implications and Adaptations

Iron supplementation is generally contraindicated during interferon therapy for viral hepatitis. Physicians treating individuals with hepatitis C virus are advised to consider a strategy of iron reduction, including dietary changes and modification of the nutritional support regimen to minimize iron intake, as well as more direct interventions, such as phlebotomy.

Levothyroxine and Related Thyroid Hormones

L-Triiodothyronine (T_3): Cytomel, liothyronine sodium, liothyronine sodium (synthetic T_3), Triostat (injection).

Levothyroxine (T_4): Eltroxin, Levo-T, Levothroid, levothyroxine (synthetic), levoxin, Levoxyl, Synthroid, thyroxine, Unithroid.

L-Thyroxine and L-triiodothyronine ($T_4 + T_3$): animal levothyroxine/liothyronine, Armour Thyroid, desiccated thyroid, Westhroid.
L-Thyroxine and L-triiodothyronine (synthetic $T_4 + T_3$): Euthroid, Euthyral, liotrix, Thyar, Thyrolar.
Dextrothyroxine (Choloxin).
Evidence: Ferrous sulfate; levothyroxine.

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**
◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**
≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Coadministration Risk

Probability: **2. Probable**
Evidence Base: ● **Consensus**

Coadministration Benefit

Probability: **3. Possible**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Limited but pharmacologically sound evidence indicates that thyroxine and iron (as ferrous sulfate) can bind to form a poorly soluble, stable complex when ingested simultaneously. Consequently, dietary and supplemental iron may reduce the GI absorption of oral levothyroxine, potentially adversely affecting therapeutic response in patients being treated for primary hypothyroidism.[49,179] Simultaneous intake could also contribute to iron depletion in susceptible individuals by impairing iron absorption.

Iron deficiency may contribute to decreased thyroid hormone synthesis and impaired thermoregulation.[180] Iron coadministration may enhance thyroid function, particularly in individuals with iron depletion or deficiency.

Research

Campbell et al.[179,181] observed that the addition of ferrous sulfate to levothyroxine in vitro will produce a poorly soluble, purple, iron-levothyroxine complex.

Clinical observations suggest that a similar pharmacokinetic interaction occurs with in the human gut and is likely to impair absorption and bioavailability of both agents when ingested within the allotted time frame. Thus, in an experiment involving 14 patients with established primary hypothyroidism on stable thyroxine replacement, Campbell et al.[179] observed a reduction in the efficacy of thyroid hormone, as indicated by an increase in thyroid-stimulating hormone (TSH) levels from 1.6 to 5.4 mU/L (although the free thyroxine index did not change significantly), when ferrous sulfate (300 mg) and the usual thyroxine dose were simultaneously ingested for a 12-week period. Thus, 9 of the 14 patients demonstrated an aggravation of their hypothyroid symptoms.

Iron deficiency anemia has been associated with lower plasma thyroid hormone. Beard et al.[180] conducted several intriguing clinical trials looking at the synergistic relationship between iron administration and thyroid function. In an experiment, they exposed 10 women with iron deficiency anemia, eight with depleted iron stores (nonanemic), and 12 control women, all of similar percentage body fat, to a 28° C water bath to test the hypothesis that iron deficiency anemia impairs thermoregulatory performance. They observed that iron administration given to iron-deficient women was associated with improved thyroid function, as indicated by partially normalized plasma thyroid hormone concentrations, and decreased need for thyroid medication. Later, they found that 27 mg/day of iron supplementation helped maintain normal thyroid hormone levels in obese patients put on a very-low-calorie diet.[182] However, using a rodent model, these researchers also found that plasma thyroid hormone kinetics in iron deficiency anemia are corrected by simply providing more thyroxine.[183]

Reports

Schlienger[184] reported the case of a woman with hypothyroidism, stable on levothyroxine, who demonstrated a significant elevation in TSH levels after administration of ferrous sulfate. Subsequently, the dosage of her levothyroxine was raised from 175 to 200 µg per day. In another case, Shakir et al.[184a] described a patient with primary hypothyroidism whose previously effective dose of levothyroxine sodium was impaired subsequent to her beginning treatment with ferrous sulfate. Initially, the patient was restabilized by increasing the dose of L-thyroxine. However, she later became hyperthyroid at that higher dosage level when she discontinued the iron supplementation.[184]

Clinical Implications and Adaptations

Physicians prescribing exogenous thyroid hormone preparations to individuals with primary hypothyroidism are advised to inform these patients to avoid unsupervised iron supplementation and, when concurrent iron administration is indicated by established iron deficiency or depleted iron stores, to separate intake by at least 2 hours to avoid pharmacokinetic interaction that could reduce absorption and bioavailability of both agents. Because hypothyroidism and iron deficiency anemia may coexist, more frequent thyroid function testing is recommended in patients treated concurrently with iron and L-thyroxine. Research suggests that individuals wanting to enhance thyroid function and increase thermogenic effects may benefit from concomitant iron, especially if they have been diagnosed with iron deficiency.

Methyldopa

Methyldopa (Aldomet); combination drugs: methyldopa and chlorothiazide (Aldoclor); methyldopa and hydrochlorothiazide (Aldoril).
Evidence: Ferrous gluconate, ferrous sulfate.

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**
◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**
≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **2. Probable**
Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Limited but consistent research has found that iron binds strongly to methyldopa, producing ferric iron–methyldopa complexes, and thereby reduces the absorption and bioavailability of both the methyldopa and the iron salt.[49,185]

Thus, the pharmacokinetic interaction could reduce the antihypertensive effects of methyldopa and might contribute to compromised iron status, particularly in individuals with iron deficiency or susceptible to depleted iron stores.

Ferrous iron, such as ferrous sulfate, is formed from ferric iron when it is reduced under the influence of the acidic pH of the GI environment. However, ferrous iron undergoes auto-oxidation to the ferric form in the presence of methyldopa and levodopa. The formation of these complexes is rapid at high pH (i.e., 9), whereas the rate slows considerably as the pH is lowered (e.g., 4). A variety of iron-methyldopa complexes can be formed between pH 4 and 9. Complexation is absent below pH 2. Together, these processes can result in both catechol oxidation and production of the toxic hydroxyl radical.[96]

Research

Campbell et al.[186] conducted a randomized crossover trial involving 12 normal subjects in which they administered a 500-mg tablet of methyldopa (2.37 mmol) with and without ferrous sulfate (325 mg) and measured absorption and excretion of methyldopa. When ferrous sulfate and methyldopa were coadministered, they observed a decrease in the proportion of methyldopa excreted as "free" methyldopa (49.5% vs. 21.1%), a significant increase in the proportion excreted as methyldopa sulfate (37.8% vs. 65.8%), and a decrease in the percentage of methyldopa absorbed (29.1% vs. 7.88%). Together these factors resulted in an 88% reduction in the quantity of "free" methyldopa excreted. Ferrous gluconate (600 mg) produced similar effects. These researchers also found that concurrent intake of ferrous sulfate and methyldopa for 2 weeks produced an increase in both systolic and diastolic blood pressure in four of five hypertensive subjects receiving chronic methyldopa therapy, with substantial increases in blood pressure seen in three of the patients. A decrease in blood pressure occurred in all patients after ferrous sulfate was discontinued.[186]

Subsequently, Campbell[188] and another team used a rat model to investigate the mechanism(s) by which ferrous sulfate (and sodium sulfate) reduces methyldopa absorption. They observed that ferrous sulfate reduced methyldopa absorption by 52.9% when they injected solutions of 14C methyldopa alone and with ferrous sulfate or sodium sulfate in vivo into closed duodenal segments. In the presence of methyldopa, iron in its ferrous form rapidly oxidizes to the ferric form, in vitro. "The ferric form of iron binds strongly to methyldopa, presumably resulting in the decreased methyldopa absorption." Methyldopa was stable in vivo and in vitro, in the presence of ferrous sulfate and sodium sulfate.

Clinical Implications and Adaptations

Physicians prescribing methyldopa are advised to inform patients to avoid unsupervised iron supplementation and, when concurrent iron administration is indicated by established iron deficiency or depleted iron stores, to separate intake by at least 2 hours to avoid pharmacokinetic interaction that could reduce absorption and bioavailability, and thus therapeutic activity, of methyldopa. Concomitant use, with simultaneous or proximate intake, could also potentially, over time, contribute to or aggravate iron deficiency or depletion of iron stores in susceptible individuals.

Neomycin

Neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin).

Interaction Type and Significance

≈◇◇ **Drug-Induced Nutrient Depletion, Supplementation Contraindicated, Professional Management Appropriate**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **2. Probable**

Evidence Base: **○ Preliminary**

Effect and Mechanism of Action

Neomycin may impair the absorption of iron and many other nutrients.[77,187]

Research

Jacobson et al.[188] coadministered neomycin and ferrous citrate to six nonanemic subjects in an experimental malabsorption syndrome study. They observed marked reduction in iron absorption in four subjects but increased iron absorption in the other two subjects, both of whom initially demonstrated low serum iron levels. These findings suggest that an individual's initial iron status may play a pivotal role in their response to iron absorption under the influence of neomycin.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing neomycin for an extended period are advised to monitor iron status and consider the potential need for iron supplementation in individuals susceptible to iron depletion. Oral intake should be separated by at least 2 hours if iron supplementation is determined to be clinically appropriate for a given patient. However, it is generally inappropriate to administer iron during an infection because iron may enhance pathogenic activity and contribute to the inflammatory process. Short-term use, such as preparation for surgery using oral neomycin, is unlikely to result in clinically significant iron deficiencies.

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCept 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).

Effect and Mechanism of Action

Oral contraceptive (OC) use is associated with decreased menstrual blood loss and potentially a reduced need for supplemental iron if increased iron stores result.

Research

The volume of blood loss associated with menstrual flow is usually decreased among certain women using OCs, but evidence of associated benefits in iron stores is less definite. Several early studies and reviews reported that OCs have beneficial effects on iron status, even though clinical research investigating the effects of OCs on iron metabolism was largely scarce.[189-191] For example, in 1984, Tyree[192] presented the conventional position in summarizing that OCs have been "shown to decrease the physiologic levels of six nutrients—riboflavin, pyridoxine, folacin, vitamin B_{12}, ascorbic acid and zinc." However, they followed with the optimistic conclusion: "Women who take OCs and have adequate diets need little or no supplemental vitamins." After further noting that OCs are associated with increased levels of vitamin C, iron, copper, and vitamin A, the author suggested: "Vitamin and mineral increases caused by OCs do not require treatment." Thus, iron supplementation would be considered less important to women using OCs and experiencing decreased menstrual blood loss than to those not having their menstrual processes altered with exogenous hormones.

Frassinelli-Gunderson et al.[193] compared serum ferritin and other parameters of iron status in 46 women using OCs for 2 or more years continuously and 71 women who never took OCs. They found that the mean serum ferritin level for the OC users was significantly higher, 39.5 ng/mL, compared to a mean level of 25.4 ng/ml in the control group. Serum transferrin, serum iron, TIBC, mean corpuscular hemoglobin (MCH), and MCH concentration (MCHC) levels were also significantly greater among the OC users. However, significantly lower RBC and hematocrit levels were found for OC users, whereas other parameters, such as hemoglobin, mean corpuscular volume (MCV), and percent transferrin saturation, were not significantly different between the groups. OC users also reported decreased menstrual cycle blood losses and a higher heme iron content in their diet. Palomo et al.[194] found that use of OCs was not associated with hemoglobin decrease, but they did observe a significant rise in saturation of transferrin. Masse and Roberge[195] investigated the effect of low-dose OC use for at least 1 year on iron metabolism and body iron status in 64 active and healthy adult women. The serum iron concentration was significantly higher in OC users than an age-matched control group. However, they found that serum ferritin, a marker for body iron stores, was marginal in both OC users and control subjects, even though mean dietary iron intake was adequate in both groups. These researchers noted that this finding indicated an underlying "high prevalence of deficient-iron reserves among subjects" that was not correlated to dietary iron content. These researchers concluded that their findings "commanded a discussion on the pertinence of evaluating the total dietary iron intake and on the sensitivity of biochemical methods used to assess the iron status."[195]

Steegers-Theunissen et al.[196] conducted a study of the effects of long-term use of OCs containing less than 50 µg of estrogen (sub-50 OCs) on the kinetics of folic acid monoglutamate, vitamin B_{12} levels, and iron status in 29 OC users and in 13 non-OC-user controls. OC users showed significantly higher TIBC. The OC users also demonstrated significantly lower serum vitamin B_{12} concentrations and significantly lower median serum folate concentration at 210 minutes after oral folate loading compared with the control group, but the authors concluded that even with these "significant effects upon folate kinetics and vitamin B_{12} levels, the folate and vitamin B_{12} status does not seem to be at risk."[196]

Mooij et al.[197] compared the effects of multivitamin supplementation on serum ferritin and hematological parameters in 28 women using OCs (sub-50 OCs) and 31 non-OC users over three consecutive cycles. Comparison of the baseline values on days 3 and 23 of the first cycle of the two groups revealed that the parameters of serum iron status were all significantly increased for the OC users compared to the non-OC control group, even though there were no significant different hematological parameters from OC use. Multivitamin supplementation was started on day 1 of the second cycle and continued daily throughout three consecutive cycles until the end of the study. The multivitamin was associated with a significantly decreased MCHC in both groups, increased MCV, and significantly increased serum iron and TIBC, whereas serum ferritin decreased during multivitamin supplementation and hematocrit and MCH remained unaltered.

Recent reviews continue to state that enhancement of iron status is among the noncontraceptive benefits of OCs.[198,199] However, human research has yet to emerge investigating the clinical implications of apparent pharmacogenomic variability in responses to synthetic, exogenous hormones such as OCs and their influence on menstrual flow, blood loss, and iron metabolism.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing OCs are advised to monitor the iron status of these female patients with periodic assessment of serum ferritin, ferritin saturation, and serum transferrin receptor levels. Increased iron levels in the blood are not necessarily a problem, but decreased monthly blood loss could potentially result in increased iron stores over time. Consequently, premenopausal women using OCs may have a decreased need for supplemental iron. Evaluation of iron status is essential before initiation of iron supplementation. Regular monitoring of folate and vitamins B_{12} and B_6 is also recommended in such women, and preventive supplementation is usually advisable.

Penicillamine

Penicillamine (D-Penicillamine; Cuprimine, Depen).

Interaction Type and Significance

✗✗ Minimal to Mild Adverse Interaction—Vigilance Necessary

◇◇ Impaired Drug Absorption and Bioavailability, Precautions Appropriate

⊕✗ Bimodal or Variable Interaction, with Professional Management

≈≈ Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management

Probability:
1. Certain

Evidence Base:
● Consensus

Effect and Mechanism of Action

The chelation function of penicillamine is central to its primary pharmacological action in therapeutic application. Penicillamine and iron bind together, thereby increasing iron

excretion and impairing bioavailability and reducing therapeutic activity of penicillamine.[200]

Penicillamine may be used to treat iron overload. Conversely, chelation therapy with penicillamine aimed at removal of other metals could induce or exacerbate depleted iron stores if compensatory nutrient augmentation is appropriate but not provided.

Research

After administering single 500-mg oral doses of penicillamine to six healthy men, Osman et al.[201] observed that penicillamine levels were reduced to 35% of those from a fasting dose. Stockley[77] reported that the absorption of penicillamine can be reduced as much as two-thirds by the concurrent use of oral iron preparations.

Reports

Harkness and Blake[202] described four cases of penicillamine-induced kidney damage that occurred when concomitant iron therapy was stopped, presumably as a result of increased penicillamine absorption and toxicity.

Clinical Implications and Adaptations

Physicians prescribing penicillamine therapy are advised to question patients regarding use of supplements containing iron and other minerals and to caution against initiation of such substances or their abrupt, unsupervised discontinuation. Chelation with penicillamine or other agents requires appropriate training and proper monitoring. Assessment of iron status is appropriate, and clinical responses will vary accordingly.

During the course of penicillamine therapy, iron deficiency can often develop, especially in children and menstruating women. In Wilson's disease, this may be a result of adding the effects of the low-copper diet, which is probably also low in iron, and the penicillamine to the effects of blood loss or growth. In cystinuria, a low-methionine diet may contribute to iron deficiency because it is inherently low in protein.

In certain circumstances, physicians who administer penicillamine for chelation of copper or other metals or for other clinical applications should coadminister minerals of nutritional importance in accordance with the therapeutic strategy and individual patient needs. When properly administered, penicillamine chelation is considered unlikely to result in adverse reactions from iron depletion. Great caution needs to be exercised when changing the level of iron intake in individuals taking penicillamine. Adverse reactions have been reported in which the prescribing physician was unaware that a patient was using concomitant supplemental iron and responded to the lack of therapeutic response to penicillamine by increasing the drug dose, after which the patient discontinued the self-prescribed iron supplementation.

Orally administered iron has been shown to reduce the effects of penicillamine. If necessary, iron may be given in short courses, but at least 2 hours, or preferably 8 hours, should elapse between administration of penicillamine and oral intake of iron supplements or other iron-containing products.

Note: Tetrathiomolybdate is much less toxic than penicillamine (or trientine) and is emerging as the copper chelator of choice for Wilson's disease. However, it has not yet obtained final approval as a new drug. Tetrathiomolybdate probably has the same interaction with iron as the other copper chelators, but substantive evidence is lacking.

Sulfasalazine

Sulfasalazine (Salazosulfapyridine, salicylazosulfapyridine, suphasalazine; Apo-Sulfasalazine, Azulfidine, Azulfidine EN-Tabs, PMS-Sulfasalazine, Salazopyrin, Salazopyrin EN-Tabs, SAS).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable** or **1. Certain**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Despite long-standing clinical application, scientific understanding of sulfasalazine, its mechanisms, and actions is incomplete. Sulfasalazine is a prodrug that is broken down by gut bacteria into 5-aminosalicylic acid (5ASA) and sulfapyridine. Although the therapeutic activity of 5ASA has been established to some degree, controversy surrounds the role and significance of sulfapyridine. A systemic immunosuppressant effect appears to be involved, but much of the anti-inflammatory activity may result from local effects on the bowel. After oral administration, 33% of the sulfasalazine is absorbed, about 33% of the 5ASA is absorbed, and all the sulfapyridine is absorbed.

Iron and sulfasalazine tend to bind in the digestive tract to form a chelate that is poorly absorbed. Consequently, the concurrent ingestion of these substances can interfere with metabolism of the prodrug into its constituents and lead to their decreased absorption and bioavailability, as well as that of iron.[203]

Research

Clinical research directly investigating the interaction between sulfasalazine and iron is limited. However, the pharmacological literature accepts the existence of this pharmacokinetic interaction as representing a consensus position, based on the principles involved and general knowledge of the agents.

Iron depletion resulting from chelation by concomitant sulfasalazine has not been studied per se. Such an adverse effect on iron status is not improbable, even with the normal physiological controls on iron levels and variable absorption rates, in light of the typically extended duration of standard sulfasalazine use. Clinical concern for iron deficiency is reasonable given the high incidence of blood loss and tissue iron depletion in individuals being treated with sulfasalazine for conditions such as ulcerative colitis or Crohn's disease. Thus, long-term sulfasalazine therapy and simultaneous oral iron intake in the face of iron deficiency could theoretically contribute to lack of tissue repletion, if care is not taken to separate intake of the two agents. Furthermore, evidence is lacking to determine whether or not long-term oral sulfasalazine therapy might cause or aggravate iron deficiency in certain persons, such as menstruating women, by preventing dietary iron absorption.

Evidence is lacking as to interactions between iron and other members of the sulfonamide class of drugs.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing sulfasalazine are advised to inform patients of the probable pharmacokinetic interaction between

iron and the medication and to recommend separating oral intake by at least 3 hours. Such measures should allow concurrent us of both agents without interfering with the intended therapeutic activity of either. In general, conservative principles of practice warrant advising patients against taking iron supplements without specific, well-founded therapeutic need and outside the context of medical supervision and monitoring. Such cautions are particularly relevant in a patient population characterized by inflammation, even in the presence of blood loss and significant probability of anemia.

Tetracycline Antibiotics

Demeclocycline (Declomycin), doxycycline (Atridox, Doryx, Doxy, Monodox, Periostat, Vibramycin, Vibra-Tabs), minocycline (Dynacin, Minocin, Vectrin), oxytetracycline (Terramycin), tetracycline (Achromycin, Actisite, Apo-Tetra, Economycin, Novo-Tetra, Nu-Tetra, Sumycin, Tetrachel, Tetracyn); combination drugs: chlortetracycline, demeclocycline, and tetracycline (Deteclo); bismuth, metronidazole, and tetracycline (Helidac).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:

2. Probable or **1. Certain**

Evidence Base:

● **Consensus**

Effect and Mechanism of Action

Tetracycline-class medications are primarily absorbed in the stomach and upper small intestine. When ingested concurrently, tetracyclines tend to form insoluble chelates with iron salts and other polyvalent metal cations, including calcium, magnesium, and zinc. This pharmacokinetic interaction can impair absorption and bioavailability of both agents, reduce the therapeutic activity of the antibiotic, and adversely affect iron balance.[204,205]

Research

Clinical research directly investigating this interaction is limited. However, the pharmacological literature accepts this pharmacokinetic interaction as representing a consensus position based on the principles involved and general knowledge of the agents involved.

Ingestion of iron supplements or iron-rich foods within a time frame allowing for binding in the gut can depress drug levels to such a degree that their therapeutic effectiveness is significantly reduced or neutralized. This adverse interaction can be avoided by maximally separating intake to minimize contact between the agents.[77]

Iron depletion resulting from chelation by antibiotics in the tetracycline class has not been the subject of substantial study. Although plausible, such an adverse effect on iron status is highly improbable with short-term tetracycline antibiotic use, given the normal physiological controls on iron levels and variable absorption rates. However, long-term tetracycline therapy and simultaneous oral iron intake in the face of iron deficiency could theoretically contribute to lack of tissue repletion. Evidence is lacking to determine whether or not long-term oral tetracycline antibiotic therapy might cause iron deficiency in certain persons, such as menstruating women, by preventing dietary iron absorption.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Iron in the form of preparations and iron-rich foods should generally be avoided while using drugs in the tetracycline class of antibiotics. Conservative principles of practice warrant advising patients against taking iron preparations without specific, well-founded therapeutic need and outside the context of medical supervision and monitoring. Such cautions regarding iron intake are particularly relevant during an infection because iron may enhance pathogenic activity and contribute to the inflammatory process.

In cases where iron administration is warranted, physicians prescribing tetracycline antibiotics are advised to inform patients of the probable pharmacokinetic interaction between iron and the medication and to recommend separating oral intake by at least 3 hours. Such measures should allow concurrent us of both agents without interfering with the intended therapeutic activity of either. Monitoring of iron status is warranted with extended administration.

Trientine

Trientine (Trien, trienthylene tetramine; Syprine).

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability:

1. Certain

Evidence Base:

● **Consensus**

Effect and Mechanism of Action

Trientine is primarily used as a chelating agent in patients with Wilson's disease who are intolerant of penicillamine, to reduce the toxic load of excess copper on the liver, brain, and other organs. Iron from supplements or iron-rich foods can bind to trientine when ingested concurrently, thereby impairing trientine bioavailability and reducing its therapeutic activity (copper chelation) while increasing iron excretion.

Research

The chelation function of trientine is central to its primary pharmacological action in therapeutic application, and its interaction with iron is well established. Anemia is a common adverse effect associated with trientine and is more likely to occur in children, menstruating women, and pregnant women, who usually have greater needs for iron nutriture than other patients.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although clinical experience with trientine is limited, it is generally agreed that use of iron and mineral nutrients concurrently with trientine may impair absorption and decrease therapeutic activity of the medication. Physicians prescribing trientine always need to ask patients about supplement use and track dietary intake patterns of copper and other minerals; close supervision and regular monitoring are essential throughout the period of drug administration. Copper levels are typically monitored in patients undergoing trientine therapy, with determination of free serum copper being the most reliable index for monitoring treatment. Adequately treated patients will usually have less than 10 µg free copper/dL serum.

Close monitoring of iron status is also warranted in patients, especially children and menstruating or pregnant women, with a known history of or a high susceptibility to iron deficiency anemia or tissue iron depletion. Except for potential interference with iron absorption caused by the chelating activity of the medication, patients following the low-copper diet appropriate to Wilson's disease are at increased risk of insufficient dietary intake of iron and other key nutrients. In patients with an established need for concomitant iron or other mineral supplementation, iron is usually prescribed in short courses, and patients are advised to separate oral intake by at least 2 hours to minimize any incidence of mutual interference.

Note: Tetrathiomolybdate is much less toxic than trientine (or penicillamine) and is emerging as the copper chelator of choice for Wilson's disease. However, it has not yet obtained final approval as a new drug. Tetrathiomolybdate probably has the same interaction with iron as the other copper chelators, but substantive evidence is lacking.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Allopurinol

Allopurinol (Oxypurinol; Aloprim, Apo-Allopurinol, Lopurin, Purinol, Zyloprim).

Allopurinol is a xanthine oxidase inhibitor used to prevent gout and to lower blood levels of uric acid in certain oncology patients undergoing chemotherapy. Allopurinol should always be used with caution during lactation and in patients with liver or renal disease.

Preliminary evidence from animal experiments indicates that concurrent intake of allopurinol and iron preparations could potentially result in an adverse interaction involving excess hepatic iron storage.[206-209] For example, in a study involving hyperthermic rat liver perfusion, Powers et al.[210] reported that allopurinol, as an inhibitor of the xanthine oxidase/reductase enzyme system, can both slow mobilization of iron from ferritin and reduce the oxidative stress associated with xanthine oxidase activity, which generates superoxide radicals. However, these effects have never been observed clinically in humans.

Based on a highly cautious approach to the limited data available, physicians might find it judicious to monitor ferritin levels in patients taking chronic allopurinol and iron supplements (in iron-deficient patients) because of a possible adverse interaction.

Amphetamines and Related Stimulant Medications

Amphetamine aspartate monohydrate, amphetamine sulfate, dextroamphetamine saccharate, dextroamphetamine sulfate; D-amphetamine, Dexedrine.
Methylphenidate (Metadate, Methylin, Ritalin, Ritalin-SR; Concerta).
Mixed amphetamines: Amphetamine and dextroamphetamine (Adderall; dexamphetamine).
Pemoline (Cylert).

Konofal et al.[211] found that iron deficiency is a clinically significant factor in many children diagnosed with attention deficit–hyperactivity disorder (ADHD), and that iron supplementation may improve therapeutic outcomes in certain cases. These findings suggest that further research is warranted into the role of iron nutriture and metabolism in the pathophysiology of ADHD and the potential for enhanced therapeutic efficacy from administration of supplemental iron along with conventional medications in cases where iron deficiency is diagnosed as a comorbid condition.

Dipyridamole

Dipyridamole (Permole, Persantine).

Dipyridamole is an older antiplatelet drug, often combined with aspirin before the availability of ticlopidine (Ticlid) and clopidogrel (Plavix) to prevent strokes, with warfarin (Coumadin) to prevent clotting after heart valve replacement, or used alone. Dipyridamole might reduce the oxidative damage caused by iron, particularly iron-induced platelet aggregation.

In vitro research indicates that dipyridamole inhibits platelet aggregation induced by iron and oxygen-derived free radicals. De la Cruz et al.[212] observed that "ferrous salts (Fe^{2+}) induced 34% platelet aggregation which was inhibited (79.6%) by a concentration of dipyridamole of 10 microM. Dipyridamole inhibited ferrous-induced lipid peroxidation with IC-50 values of 17.5 microM."

An emerging body of evidence indicates that excess iron intake by individuals who are not iron deficient might cause tissue damage that could then contribute to heart disease.[33]

Well-designed human trials might be appropriate to investigate this potential therapeutic application of dipyridamole in reducing the effects of iron-induced oxidative damage on by platelet aggregation. Administration of dipyridamole with the specific aim of countering the effects of iron is unsupported at this time and requires supportive evidence from substantive research.

Haloperidol

Haloperidol (Haldol).

Use of haloperidol is associated with decreased blood levels of iron.[213] Ben-Shachar and Youdim[214] observed that dopamine D_2 receptor subsensitivity, a feature of iron deficiency, is absent in iron-deficient rats administered haloperidol, and that biochemical and behavioral D_2 receptor supersensitivity is relatively greater than in control, haloperidol-treated animals. These researchers found that haloperidol (5 mg/kg daily for 21 days), as well as chlorpromazine (10 mg/kg daily for 21 days), caused a significant reduction (20%-25%) in liver nonheme iron stores compared with values in control rats. However, haloperidol had no effect in iron-deficient rats whose liver iron stores had been almost totally depleted. The authors interpreted these findings to suggest that lower iron levels may result in an increase in free haloperidol available to the dopamine D_2 receptor.

No definitive research has emerged to confirm the occurrence or clarify the clinical significance of this interaction between haloperidol and iron in humans. Pending more conclusive findings from well-designed clinical trials or consistent, substantive, and well-documented case reports, physicians prescribing haloperidol are advised to ask patients about their supplement use and recommend that they avoid supplements containing iron unless iron deficiency has been diagnosed. Monitoring of haloperidol levels may be warranted if iron status is altered or dietary intake significantly changes.

Methotrexate

Methotrexate (Folex, Maxtrex, Rheumatrex).

Concern has been raised that concomitant oral iron intake might alter absorption and therapeutic activity of methotrexate. In a randomized, double-blind, placebo-controlled crossover study, Hamilton et al.[215] compared the urinary excretion of unmetabolized methotrexate in 10 patients with rheumatoid arthritis who were administered methotrexate, 7.5 mg weekly,

and either ferrous sulfate, 300 mg twice daily, or placebo for 1 week. No significant difference was observed in average 24-hour urine excretion of methotrexate between the two groups.

Pending further research, the probability of a clinically significant interaction between methotrexate and supplemental iron can be considered as improbable. Nevertheless, it might be judicious to advise patients for whom both agents are medically appropriate to separate intake by at least 3 hours to avoid any as-yet undocumented pharmacokinetic interference with absorption of either agent.

Pyrimethamine/Sulfadoxine

Pyrimethamine (Daraprim); combination drug: sulfadoxine and pyrimethamine (Fansidar).

Deficiencies in vitamin A, zinc, iron, folate, and other micronutrients are responsible for a substantial proportion of malaria morbidity and mortality. Iron deficiency and *Plasmodium falciparum* malaria are the two main causes of anemia in young children in regions endemic for this disease, even though malaria infection itself does not contribute to iron deficiency. However, Stockley[77] reports that iron may delay the therapeutic activity of pyrimethamine/sulfadoxine in eradicating *P. falciparum* or *Plasmodium vivax*, the malaria parasite. Thus, the determination of nutritional status and the appropriate timing of nutritional support can be of critical importance in promoting positive clinical outcomes.

In a trial of two-by-two factorial design, Verhoef et al.[216] randomly assigned 328 anemic but symptom-free Kenyan children into four groups of equal size to receive either iron or placebo and sulfadoxine-pyrimethamine (SP) or placebo. Hematological indicators of iron status and inflammation at the end of the follow-up and occurrence of malaria attacks served as primary outcomes. Analyses were by intention to treat. These researchers observed that after 12 weeks, the groups administered iron plus SP, iron alone, or SP alone had higher hemoglobin concentrations than the group given placebo. Coadministration of iron and SP also lowered the proportion with anemia from 100% at baseline to 36% at 12 weeks, and with iron deficiency from 66% at baseline to 8% at 12 weeks. Survival analysis revealed no evidence of substantially increased risk of malaria after iron administration.

Desai et al.[217] conducted a randomized, placebo-controlled trial involving 546 anemic children age 2 to 36 months in a malaria-endemic area of western Kenya. All children used bednets and received a single dose of SP on enrollment, followed by either intermittent preventive treatment (IPT) with SP at 4 and 8 weeks and daily iron for 12 weeks, daily iron and IPT with SP placebo, IPT and daily iron placebo, or daily iron placebo and IPT with SP placebo (double placebo). After assessing the mean hemoglobin concentration at 12 weeks, compared with that for the double-placebo group, these researchers determined that IPT reduced the incidence of malaria parasitemia and clinic visits, but iron provided no additional preventive benefit. Furthermore, although the combination of IPT and iron was most effective in treating mild anemia and IPT prevented malaria, with IPT "the hematological benefit . . . added to that of a single dose of SP and bednet use was modest."[217] However, in a subsequent cluster-randomized clinical trial investigating iron dosing in the treatment of anemia in preschool children, this research team found that, after initial antimalarial treatment with a single SP dose, 6 weeks of daily iron supplementation results in superior hematological responses, particularly hemoglobin concentrations, than does twice-weekly iron administration, regardless of whether adherence can be ensured.[218]

Iron supplementation can play an important role in the recovery of patients, especially malnourished children, after treatment for malaria. However, iron coadministration in cases of anemia associated with malaria is controversial. Introduction of weekly iron may be appropriate starting 2 weeks after the malaria is controlled. However, in children who have been severely malnourished or ill, especially edematous, it is advisable to withhold iron until the child is recovering (e.g., loss of edema, weight gain, no hepatomegaly), even if iron deficiency anemia has been diagnosed. Iron should not be administered until they regain their appetite, regardless of the hemoglobin level. These children generally have very low levels of transferrin, a high iron saturation, stainable iron in their marrow and liver, and high levels of iron excretion after desferrioxamine. Thus, iron should be initiated when the children start to grow rapidly, have resynthesized their transferrin, and have reversed the oxidized intracellular environment. Measuring GSH and NADPH longitudinally can guide the timing of iron introduction. Monitoring for iron overload is warranted, but the probability of this occurring in the affected patient populations is low. Life-threatening anemia (in the range of 3 g/dL) will usually require transfusion, but great caution and careful supervision are required so as not to precipitate cardiac failure.

Folic acid administration is warranted in many individuals because anemia is endemic in susceptible populations, particularly children, and the causes of anemia are multifactorial.

Stanozolol

Stanozolol (Winstrol).

In a letter, Taberner[219] reported that stanozolol therapy was associated with iron deficiency. Sixteen patients taking 10 mg stanozolol daily in a trial of fibrinolytic enhancement therapy in intermittent claudication experienced a significant fall in mean cell hemoglobin (MCH) after 3 months of treatment. The red blood cell (RBC) count did not change significantly, but hemoglobin (Hb) and mean cell volume (MCV) also declined, contrary to an expected rise in Hb and RBC count. After exclusion of one patient who was iron deficient at baseline, six patients remained on therapy for a year or more. Four of these had dietary histories indicating insufficient iron nutriture and demonstrated RBC indices suggestive of iron deficiency, later confirmed by biochemical measurement and ferritin assay. In one of these four patients, stanozolol was discontinued without iron supplementation; the RBC indices and iron status returned to normal. No GI bleeding or evidence of fecal blood loss was observed to account for the iron deficiency. The increase in muscle bulk induced by the anabolic steroids was hypothesized to cause utilization of iron at the expense of Hb, subsequently reflected in a change in RBC Hb. The author concluded by recommending that "patients taking stanozolol for long periods should have RBC indices and liver function monitored regularly".[219]

Warfarin

Warfarin (Coumadin, Marevan, Warfilone).

Iron (as well as magnesium and zinc) can bind with warfarin, potentially decreasing absorption and activity of both agents.[220] However, these potential effects have never been confirmed by conclusive findings from well-designed clinical trials or consistent, substantive, and well-documented case reports.

According to a nested case-control analysis of multiple linked health care databases conducted by Canadian researchers, patients taking warfarin at the same time as selective COX-2 inhibitors or nonselective NSAIDs have an increased risk of hospitalization for upper GI hemorrhage.[161] Patients in such

situations would be at increased risk of iron deficiency anemia or tissue iron depletion because of chronic blood loss.

Although the pharmacological principles of an interaction involving binding of warfarin by concurrent ingestion of common mineral nutrients are well founded, the frequency of occurrence and clinical significance of this potential interaction are uncertain. Physicians prescribing warfarin should be aware of the possible risk of reduced effectiveness of treatment in patients taking nutrient formulations containing iron, magnesium, and zinc. Separating oral intake of warfarin and such minerals by at least 2 hours will usually provide adequate protection from unwanted interference.

NUTRIENT-NUTRIENT INTERACTIONS

Calcium

Calcium in foods or supplements may reduce absorption of iron, especially heme iron. When ingested concurrently, substantial doses of calcium (as carbonate, phosphate, or citrate) can significantly decrease iron absorption, by as much as 62%.[221-226] The available findings suggest that the effects of this pharmacokinetic interaction may be clinically insignificant at calcium intake levels of 1000 to 1500 mg/day, as indicated by serum ferritin levels, in individuals who are neither iron deficient nor demonstrating malabsorption.[227-229]

Available evidence indicates that the absorption of iron in multimineral formulations containing iron and calcium is probably not significantly altered. Nevertheless, separating oral intake of calcium and iron supplements by 2 hours or more may reduce the adverse effects of potential pharmacokinetic interference with absorption of either or both nutrients.

Copper

Iron and copper exhibit a multifaceted synergistic relationship within human physiology. Adequate copper nutriture appears necessary for normal iron absorption and metabolism, iron transport to the bone marrow, and RBC formation. Animals deficient in copper tend to accumulate hepatic iron. Anemia is a clinical sign of copper deficiency. However, simultaneous oral administration of copper and iron in large doses may impair the absorption of either or both nutrients.

Fiber

When consumed concurrently, fiber (particularly phytic acid–containing fiber, as from cereal beans) can reduce iron absorption. Other fibers, such as that from psyllium seed, have minimal if any effect on iron or other mineral absorption.

Folate

Iron and folate work together in many aspects of human physiology, particularly RBC formation and function. Coadministration of iron and folate is common in the prevention and treatment of anemia, but proper diagnostic assessment is essential to determine causal factors.

Thompson et al.[230] at the Cancer Foundation of Western Australia found a protective association between maternal iron or folate supplementation in pregnancy and the risk of common acute lymphoblastic leukemia (ALL) in a population-based case-control study of children from birth to age 14 years and living in Western Australia from 1984 to 1992. For iron alone, the odds ratio was 0.75; only one mother took folate without iron. Further analyses of folate use with or without iron showed that the protective effect varies little by time of first use of supplements or for how long they were taken.

Manganese

When iron and manganese are ingested together, the absorption of manganese may be impaired. In a study involving 47 women, Davis et al.[231] observed that increased dietary intake of nonheme iron, typical of supplemental formulations, was associated with decreased manganese status. Notably, foods that contain significant amounts of manganese (green vegetables, breads, and cereals) often have significant amounts of nonheme iron and therefore greater probability of impaired manganese absorption. In contrast, heme iron intake was positively correlated with hematological status and had no consistent effect on nutritional status in regard to manganese. Similarly, Finley[232] reported that young women with high iron status, as indicated by serum ferritin concentration, had relatively poor absorption and retention of manganese.

In a review of manganese research, Freeland-Graves[233] recommended that oral intake of iron and manganese be separated by 4 hours, or taken at a different time of day, to avoid absorption problems. However, these findings might also suggest that multimineral formulations containing both iron and manganese could be more effective in preventing manganese deficiency than iron-only preparations.

Pancreatic Enzymes

Iron absorption may potentially be reduced by concomitant use of pancreatic extracts.

Phosphorus/Phosphate Supplements

Calcium phosphate (Tribasic); potassium phosphate; sodium phosphates.

After oral administration, divalent cations, such as iron salts, can bind to orally administered phosphate in the GI tract, potentially reducing the absorption and bioavailability of phosphate supplements. Administering oral phosphate preparations at least 1 hour before, or 2 hours after, oral iron salt intake can reduce the probability and significance of this interaction and maximize the therapeutic effect of the phosphate.

Taurine

In a double-blind, randomized trial involving 51 female university students with iron deficiency anemia (IDA), Sirdah et al.[234] reported a possible beneficial additive effect associated with coadministration of oral taurine (1000 mg/day) and slow-release iron sulfate (325 mg/day), as indicated by changes in hemoglobin concentrations and normalization of iron deficiency markers. No significant adverse effects were reported. They noted that, at baseline, mean serum taurine was significantly lower in the IDA subjects than in the controls.

Vitamin A

Vitamin A improves the absorption and utilization of iron, and vitamin A deficiency may exacerbate iron deficiency anemia. Vitamin A also prevents the inhibition of iron absorption by coffee and tea.[228] Two studies, one focusing on iron metabolism and protein status in children and the other involving pregnant women in West Java with nutritional anemia, found that coadministration of vitamin A enhanced treatment of iron deficiency anemia and improved iron status. The concomitant administration of vitamin A and iron ameliorated anemia more effectively than either iron or vitamin A

alone.[235,236] Likewise, in a study of Mexican preschoolers at high risk for deficiency of vitamin A, iron, and zinc, Muñoz et al.[237] demonstrated that supplementation with iron, or iron and zinc, improved indicators of vitamin A status. More recently, Zadik et al.[237a] reported that combined vitamin A and iron supplementation is as efficient as hormonal therapy in constitutionally delayed children.

Vitamin C (Ascorbic Acid)

Vitamin C, in supplemental formulations or vitamin C–rich foods, can strongly enhance the absorption of nonheme iron in the GI tract by reducing dietary ferric iron (Fe^{3+}) to ferrous iron (Fe^{2+}), forming a highly absorbable iron–ascorbic acid complex, and increasing bioavailability of the iron twofold to threefold.[62,77,238-241] This effect, however, appears to be influenced by gastric pH, bile function, and other dietary constituents, very dose dependent, and relatively minor at ascorbic acid doses under 200 mg, even in individuals with low iron stores.[62,242,243] However, ascorbic acid can prevent the dose-dependent inhibitory effects of polyphenols and phytates on nonheme-iron absorption.[244] Furthermore, ascorbate stabilizes the iron cores of ferritin in cells and impairs ferritin degradation and autophagic uptake of ferritin clusters into lysosomes.[245]

Iron deficiency anemia affects one third to half of children in the developing world. Zlotkin et al.[6] found that adding "sprinkles," ferrous fumarate and ascorbic acid microencapsulated in a thin, soy-based coat, to weaning foods can be an effective tool in reducing rates of anemia in susceptible children.

Vitamin E

Evidence: Ferrous sulfate, iron dextran complex.
Extrapolation: Ferric gluconate, ferrous fumarate, ferrous gluconate, iron sucrose, polysaccharide-iron complex.

Concomitant administration of vitamin E may diminish the therapeutic effects and mitigate the adverse effects of iron salts.

In an early study, Melhorn and Gross[246] observed a decrease in the hematological response to iron administration (iron dextran, 5 mg/kg/day for 3 days, followed by oral ferrous sulfate beginning on the seventh day) in children with iron deficiency anemia when oral vitamin E (200 IU) was coadministered on iron days 1 through 3. They reported that the reticulocyte response in patients receiving vitamin E was 4.4%, versus 14.4% in those not receiving vitamin E.

Large doses of iron may increase requirements for vitamin E. Roob et al.[20] found that the antioxidant activity provided by concomitant vitamin E can attenuate oxidative stress induced by IV iron in patients on hemodialysis.

Zinc

When administered orally, at the same time, iron and zinc can mutually reduce absorption. In particular, the ingestion of iron in high doses on an empty stomach can inhibit the absorption of zinc from simultaneous oral intake. However, supplemental iron does not appear to significantly inhibit zinc absorption in the presence of food. Similarly, iron-fortified foods do not appear to significantly alter zinc absorption.[228,229]

Zago and Oteiza[247] reported that the antioxidant activity of zinc may ameliorate oxidative stress induced by iron. Furthermore, the inhibition of Fe^{2+}-induced lipid oxidation by either alpha-tocopherol or epicatechin was increased by the simultaneous addition of zinc.

HERB-NUTRIENT INTERACTIONS

Herbs Containing Tannins And Polyphenols

Black tea, green tea *(Camellia sinensis)*.
Coffee *(Caffea arabica, Caffea canephora, Caffea robusta)*.

Coffee, black or green tea, chamomile, and many other plants, some commonly consumed as beverages, contain significant levels of polyphenols and tannins that can significantly impair absorption of iron by binding with iron to form insoluble complexes. In particular, phenolic compounds from plants consumed as foods and beverages are released during digestion and can complex with nonheme iron in the intestinal lumen, rendering it unavailable for absorption.

Black tea polyphenols are more inhibitory than the polyphenols from herb teas, cocoa, or wine, possibly because of their higher content of galloyl esters. Hurrell et al.[248] studied the effects of different polyphenol-containing beverages on nonheme iron absorption from a bread meal, containing a mere 2.1 mg iron, in adult human subjects from the erythrocyte incorporation of radiolabeled Fe. They tested beverages that contained different polyphenol structures and were rich in either phenolic acids (e.g., chlorogenic acid in coffee), monomeric flavonoids (as found in chamomile [*Matricaria recutita* L.], vervain [*Verbena officinalis* L.], lime flower [*Tilia cordata* Mill.], peppermint [*Mentha piperita* L.], and other common herb teas, as well as pennyroyal [*Mentha pulegium* L.]; or complex polyphenol polymerization products (such as black tea and cocoa). All beverages were potent inhibitors of iron absorption and reduced absorption in a dose-dependent fashion depending on the content of total polyphenols. Compared with a water control meal, beverages containing 20 to 50 mg total polyphenols per serving reduced iron absorption from the bread meal by 50% to 70%. Herbal beverages containing 100 to 400 mg total polyphenols per serving reduced iron absorption by 60% to 90%. Black tea inhibited iron absorption by 79% to 94%, peppermint tea by 84%, pennyroyal by 73%, cocoa 71%, vervain 59%, lime flower 52%, and chamomile by 47%. Black tea was more inhibitory than cocoa, chamomile, vervain, lime flower, and pennyroyal at an identical concentration of total polyphenols. The addition of milk to coffee or tea did not significantly influence their inhibitory nature. Despite the relatively low dose of iron tested, the researchers concluded that these findings demonstrate that black tea, coffee, cocoa, and a variety of herbal teas can be potent inhibitors of iron absorption.[248]

The effect of coffee's inhibition of iron absorption from supplemental or dietary sources may contribute to iron deficiency anemia, particularly in pregnant women; such effects might potentially reduce the levels of iron in breast milk to a clinically significant degree. Morck et al.[249] demonstrated that coffee inhibits iron absorption in a concentration-dependent fashion with simultaneous ingestion and when coffee was taken 1 hour later in iron-replete human subjects. In a controlled study involving pregnant low-income women in Costa Rica who consumed more than 450 mL coffee daily, Muñoz et al.[250] observed an association between coffee consumption and reductions in maternal hemoglobin levels and hematocrits, as well as similar effects in their infants, despite daily supplementation with ferric sulfate 200 mg (i.e., 60 mg elemental iron) and folate (500 µg). Iron deficiency anemia (hemoglobin < 11 g/dL) was demonstrated in almost one quarter of the coffee-drinking mothers compared with none of the non-coffee-drinking mothers in the control group. Iron levels in breast milk were one-third lower in mothers who consumed coffee.

Merhav et al.[251] report a much higher incidence of microcytic anemia among infants in Israel who consumed 50 to 750 mL tea per day (median, 250 mL). On studying 122 healthy infants, they found that the percentage of tea-drinking infants with microcytic anemia was significantly higher than that of the non–tea-drinking infants (32.6% vs. 3.5%). The tea drinkers had significantly lower mean Hb and MCV levels than the non–tea drinkers. However, in a study involving 10 iron-deficient children who consumed 150 mL of tea per day, Koren et al.[252] reported no significant alterations in absorption of iron at daily doses of 2 to 15.8 mg/kg.

These preliminary findings suggest a pattern of impaired iron absorption and bioavailability of potentially meaningful dimensions, even in the presence of iron supplementation. Further research is warranted to determine the incidence and clinical import of these observations. In the meantime, healthcare providers are advised to recommend limited consumption of coffee, tea and other tannin-containing beverages by pregnant or lactating women as well as nursing infants or children drinking herbal beverages.

Samman et al.[253] reported that green tea or rosemary extract, added to foods, reduces nonheme iron absorption by as much as 26%. This apparently significant interaction may be clinically efficacious in the treatment of individuals with iron overload diseases, such as hemochromatosis.

The 256 citations for this monograph, as well as additional reference literature, are located under Iron on the CD at the back of the book.

Magnesium

Nutrient Name: Magnesium.
Elemental Symbol: Mg.

Summary

Drug/Class Interaction Class	Mechanism and Significance	Management
Albuterol Beta-2-adrenoceptor agonist bronchodilators ⊕⊕	Supplementation enhances albuterol efficacy and counters hypomagnesemia. Variable significance, ranging from minimal, preventive to significant, urgent.	Coadminister. Monitor.
Aminoglycoside antibiotics ≈≈/☼	Drug-induced tubular damage, impaired magnesium absorption. Magnesium important with extended therapy.	Coadminister. Monitor.
Amphetamines and stimulant medications Dextroamphetamine Methylphenidate ⊕⊕	Magnesium salts may enhance drug retention and availability; drugs may elevate magnesium levels; mutual increased effect. Improved drug kinetics and enhanced Mg status and effect on Ca/Mg ratio may benefit clinical outcomes.	Coadminister. Monitor. Possible decrease of drug dose.
Amphotericin B ≈≈≈☼	Hypomagnesemia caused by renal magnesium wasting and impaired reabsorption. Hydration and nutrients nephroprotective.	Coadminister. Monitor. Consider liposomal amphotericin B.
Bisphosphonates ◈◈/◈	Minerals and bisphosphonate chelate; reduced absorption and bioavailability. Immediate onset, usually moderate severity, gradual effect.	Modify timing to prevent chelation.
Calcium channel blockers ⊕✗/✗✗✗/✗✗/≈≈	Reduced ionic calcium availability to muscle cells; more hypotensive. Possible synergy. Caution: increased risk in pregnancy.	Consider coadministration. Closely monitor.
Cisplatin ≈≈≈/◈	Cisplatin impairs renal tubules' ability to conserve magnesium, resulting in clinically significant hypomagnesemia.	Evaluate magnesium and potassium status, renal function. Coadminister. Monitor.
Colchicine ≈≈≈	Colchicine may impair absorption of magnesium and other nutrients, potentially causing depletion and adverse effects. Plausible mechanism, but minimal evidence.	Consider supplementing with multivitamin/mineral formulation containing magenesium, with extended colchicine therapy. Separate intake.
Corticosteroids, oral ≈≈≈/◈	Magnesium depletion and impaired absorption. Associated with steroid-induced bone loss.	Supplement minerals during extended steroids.
Cyclosporine ≈≈≈/☼/◈	Severe hypomagnesemia, renal magnesium wasting, nephrotoxicity.	Coadminister. Regularly monitor renal function and RBC Mg levels.
Digoxin ≈≈≈/☼/◈/◈◈	Digoxin decreases Mg and increases loss, increasing risk of digitalis toxicity. Magnesium and digoxin may chelate; reduced absorption and bioavailability of both. Immediate and potentially severe as well as cumulative depletion effects; potential mutual interference.	Coordinated use with separated administration. Closely monitor.
Diuretics, loop and thiazide ≈≈≈/☼/◈	Diuretics inhibit magnesium absorption and increase excretion, amplifying potassium depletion. Cumulative adverse effect of mineral depletion; rapid correction may require intravenous or intramuscular administration of magnesium.	Evaluate magnesium and potassium status, renal function. Coadminister long-term. Monitor.
Estrogens Estrogen replacement therapy (ERT) Oral contraceptives (OCs) ≈≈≈/◈	Exogenous estrogen may shift magnesium to soft tissue and bone, lowering serum levels and body stores. Magnesium depletion may amplify, and supplementation may moderate, possible adverse effects from PMS to bone and heart.	Conservative to supplement for short-term and long-term preventive and protective effects.
Fentanyl ⊕⊕/☼	Coadministration of intravenous magnesium sulfate may enable reducing analgesic dosage requirements, possibly by resetting nerve activation thresholds. Encouraging preliminary research indicates further study warranted, including trials using oral magnesium.	Coadministration of magnesium, usually IV, may be beneficial. Closely monitor.
Fluoroquinolone/quinolone antibiotics ◈◈/◈	Magnesium and fluoroquinolones may chelate; reduced absorption and bioavailability of both. Evidence of potential interference derived from magnesium antacids.	Adjust timing to avoid simultaneous or close oral administration.
Foscarnet ≈≈	Renal impairment caused by foscarnet may be responsible for adverse effect on magnesium, calcium, potassium, and phosphorus. Depletion sequelae are common and can be rapid and severe.	Frequently monitor magnesium and other electrolytes. Administer magnesium as indicated.
Insulin ⊕⊕	Diabetics tend toward magnesium deficiency; magnesium can improve insulin sensitivity and secretion. Both risks and benefits tend to increase gradually.	Coadminister. Monitor.
Lithium carbonate ◈◈	Lithium and magnesium may compete. Concomitant intake may elevate magnesium levels but adverse effects unlikely. No indication of interference with drug activity.	Monitor.
Macrolide antibiotics ≈≈≈/☼	Erythromycin and other macrolide antibiotics may interfere with absorption of magnesium and other nutrients, especially with extended treatment. Mechanism plausible but evidence preliminary or inconclusive.	Consider nutrient supplementation with extended macrolide therapy. Separate intake.

Summary

Drug/Class Interaction Class	Mechanism and Significance	Management
Misoprostol ✗✗/◇◇	Probable additive effect of magnesium, increasing diarrhea. Misoprostol's adverse effects on gastrointestinal tract may be aggravated.	Temporarily avoid magnesium, if possible.
Neuromuscular blocking agents ✗✗/⊕✗/⊕⊕	Magnesium salts can increase and prolong agent effects. Unintentional additive effects may be severe; coordinated use may allow lower drug doses.	Assess magnesium status. Consider coadministration. Monitor closely.
Pentamidine ≈≈/☼	Pentamidine can decrease magnesium levels and produce adverse effects, especially on cardiac function. Evidence minimal but mechanisms reasonable.	Assess and monitor magnesium (and potassium) status initially and during treatment. Coadminister as indicated, possibly preventively.
Penicillamine ◇◇/◇/⊕✗	These agents tend to complex; may reduce magnesium absorption. Simultaneous intake may interfere with and inhibit activity of both agents. High doses of penicillamine for extended period can inactivate and deplete magnesium.	Assess magnesium status. Adjust timing to separate oral administration if magnesium strategically necessary.
Quinidine Antiarrhythmic drugs ⊕⊕/☼/≈≈	Quinidine-induced arrhythmias aggravated by electrolyte abnormalities; MgSO4 reverses torsades de pointes by unknown mechanism. Hypomagnesemia may increase quinidine adverse effects, especially with hypokalemia.	Assess magnesium and potassium status. Consider coadministration. Monitor closely.
Sodium polystyrene sulfonate (SPSS) ≈≈/◇	SPSS may alter magnesium levels and contribute to depletion. Compensatory magnesium may prevent or reverse potential adverse effects. Evidence minimal but mechanism(s) plausible.	Consider magnesium coadministration, especially if magnesium strategically significant.
Sotalol Beta-1-adrenoceptor antagonists ☼/⊕/◇◇	Magnesium salt may reduce drug absorption and availability; drug effect on magnesium (and other minerals) may increase adverse effects; MgSO4 reverses torsades de pointes by unknown mechanism. Intentional coadministration can be acute therapy or long-term supportive; unintentional interference may be gradual.	Coordinated use may be beneficial but need separate administration; closely monitor.
Sulfonylurea Hypoglycemics ✗✗/✗✗✗/⊕✗/⊕/⊕⊕	Magnesium may increase drug activity on glucose. Diabetics tend toward magnesium deficiency; Mg can improve insulin sensitivity and secretion. Enhanced drug response may excessively lower glucose or may facilitate therapeutic strategy.	Coadminister. Monitor. Titrate drug dose.
Tetracycline antibiotics ◇◇/◇/⊕✗	Tendency to chelate may reduce (or enhance) absorption of both; mixed evidence. Coadministration carries risk of (increased) adverse effects but may be efficacious in some uses.	Adjust timing to separate oral administration if magnesium strategically necessary.
Theophylline/aminophylline ◇≈≈/◇/⊕⊕	Theophylline may deplete magnesium and aggravate magnesium status. Patient population tends to be magnesium deficient, and magnesium can support therapeutic outcome.	Assess magnesium status. Consider coadministration. Monitor closely.
Warfarin Oral vitamin K antagonist anticoagulants ◇◇/✗✗/◇	Binding and formation of chelate complexes may reduce absorption and activity of both agents. Evidence mixed but suggests negligible impact on drug activity, especially with separation of oral intake. Further research warranted.	Separate intake by at least 2 hours. Monitor closely.

RBC, Red blood cell; *PMS*, premenstrual syndrome.

NUTRIENT DESCRIPTION

Chemistry and Forms

Magnesium ascorbate, magnesium aspartate, magnesium chloride, magnesium citrate, magnesium fumarate, magnesium gluconate, magnesium glycerophosphate, magnesium glycinate, magnesium hydroxide, magnesium malate, magnesium oxide, magnesium pidolate, magnesium succinate, magnesium sulfate.

Physiology and Function

Magnesium functions as a structural cofactor or as an allosteric activator of enzyme activity in more than 300 enzyme reactions in the body, including those related to the transfer of phosphate groups, all reactions that require adenosine 5'-triphosphate (ATP; i.e., mitochondrial oxidative phosphorylation), glycolysis, fatty acid oxidation and amino acid metabolism, and the replication and transcription of DNA, synthesis of RNA, and translation of messenger RNA (mRNA). Magnesium is the second most abundant intracellular cation and the fourth most prevalent cation in the body. The normal body magnesium content is approximately 1000 mmol, or 22·66 g, of which 50% to 60% resides in bone. Magnesium affects many cellular functions, including transport of potassium (K^+) and calcium (Ca^{++}) ions, and modulates signal transduction, energy metabolism, and cell proliferation. The magnesium cation (Mg^{++}) is also required for cellular energy metabolism and plays an important role in cell proliferation and membrane stabilization, nerve signal transduction, ion transport, and calcium metabolism. Magnesium decreases coagulation and acts as a calcium channel blocker. Magnesium regulates the absorption of calcium and is involved in the structural integrity of bones and teeth. If it is deficient in the bones, the bones may be dense but brittle because of poor trabecular integrity. Magnesium regulates the contractility of cardiac muscle. It is concentrated 18 times greater in heart muscle than in the bloodstream, and decreased levels in heart tissue increase susceptibility to coronary spasms. Magnesium has a relaxing effect on smooth muscle and may be helpful in relaxing the smooth muscle of the bronchioles and the arterioles. Consequently, magnesium deficiency can produce a variety of metabolic abnormalities and clinical consequences.

Serum magnesium concentration is maintained within a narrow range by the small intestine and kidneys. Total body

magnesium (TBMg) depends mainly on gastrointestinal absorption and renal excretion. Many factors regulate magnesium absorption. Intestinal absorption is inversely proportional to the amount ingested. As calcium intake decreases, Mg^{++} absorption increases. Magnesium absorption occurs primarily in the jejunum and ileum via active carrier-mediated transport (partly dependent on vitamin D and parathyroid hormone [PTH]) and passive diffusion. The rate of magnesium absorption varies from as low as 24% to as high as 85%. Plasma Mg^{++} concentration is the major regulator of magnesium reabsorption within the kidney, serving as the principal organ in magnesium regulation. About 100 mg is excreted daily into the urine. In contrast to other ions, 60% to 70% of Mg^{++} reabsorption occurs in the thick ascending loop of Henle. Even so, the distal tubule is the major site of magnesium regulation, although it normally reabsorbs only 10% of filtered Mg^{++}. Both hormonal and nonhormonal factors influence Mg^{++} reabsorption in the loop of Henle and distal tubule, including PTH, calcitonin, glucagon, and vasopressin levels; magnesium restriction; acid-base changes; and potassium depletion. In plasma magnesium self-regulatory processes, the Ca^{++}/Mg^{++}-sensing receptor induces inhibition of loop transport in response to hypermagnesemia, whereas hypomagnesemia stimulates transport. Hypercalcemia and the rate of sodium chloride reabsorption can also influence reabsorption. Under conditions of magnesium deprivation, both organs increase their fractional absorption of the nutrient. Magnesium distribution constantly but gradually shifts between stores in bone or muscle and the extracellular fluid (ECF). In situations of magnesium depletion, resulting in negative magnesium imbalance, ECF will give up the initial losses, and serum Mg^{++} concentrations will rapidly fall. A compensatory reduction will then occur in urinary Mg^{++} concentrations unless there is magnesium wasting for other reasons. Finally, over several weeks, equilibration utilizing the bone stores will take place.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Magnesium has primarily been used in, and investigated for, the treatment of cardiovascular disease, diabetes, migraine, muscular spasm and irregular contractility, osteoporosis, and premenstrual syndrome. Usage ranges from daily dietary and supplemental intake to intravenous infusion for critical care. The value of this mineral in promoting health and treating disease is gradually coming into greater appreciation, as are the implications of its involvement in interactions with pharmaceutical agents. For example, a recent large study confirmed that greater levels of dietary magnesium intake appear to be associated with a reduced risk of coronary heart disease.[1]

Possible Uses

Alcohol withdrawal, angina, anxiety, asthma, atherosclerosis, autism, cardiac arrhythmias, cardiomyopathy, cardiovascular disease, celiac disease, chronic fatigue syndrome (CFS), chronic obstructive pulmonary disease (COPD), congestive heart failure, constipation, Crohn's disease, depression, diabetes mellitus, dysmenorrhea, eclampsia, eosinophilia-myalgia syndrome, epilepsy, fatigue, fibromyalgia, gastrointestinal spasms or cramping (acute), glaucoma, hearing loss (especially noise-related), hyperactivity, hypercholesterolemia, hypertension, hypocalcemia, hypoglycemia, hypokalemia, insomnia, intermittent claudication, kidney stones, lead toxicity, low levels of high-density lipoprotein (HDL) cholesterol, menopause, migraine, mitral valve prolapse, muscle cramping (especially nocturnal), multiple sclerosis, myocardial infarction (acute), osteoporosis, premenstrual syndrome (PMS), Raynaud's disease, retinopathy, sickle cell disease, stress response, stroke, torticollis, toxemia of pregnancy, urinary urge incontinence.

Deficiency Symptoms

There is significant disagreement as to the prevalence of clinically significant, although possibly subclinical, magnesium deficiency among the healthy subpopulations in developed societies. Nevertheless, the incidence of inadequate magnesium nutriture among susceptible subpopulations is widely recognized. A survey conducted by the U.S. Department of Agriculture showed that the daily dietary magnesium intake of many Americans (up to 75%) falls below the recommended dietary allowance (RDA),[2] which would mean that magnesium is among the most commonly deficient nutrients in that population. Suboptimal magnesium intake adversely affects a wide range of tissues, particularly those of the heart, nerves, and kidneys; many experts would say that all tissues are compromised by such a status. A diet high in processed and packaged foods tends to be magnesium poor because magnesium is found predominantly in whole, unprocessed foods.

Hypomagnesemia is frequently encountered in hospitalized patients and is seen in up to two thirds of patients admitted to intensive care units.[3] One survey of predominantly female urban African Americans found a 20% overall prevalence of magnesium deficiency.[4] Chronic degenerative diseases, such as diabetes, hyperlipidemia, hypertension, renal disease, asthma, and heart failure, are often associated with, and even potential causes of, magnesium deficiency, usually resulting from loss of magnesium from the gastrointestinal (GI) tract or the kidney. Alcoholism, severe burns, and other debilitative or traumatized states are also strongly linked to compromised magnesium status. Other GI causes include protein-calorie malnutrition, intravenous administration of Mg-free fluids and total parenteral nutrition, acute or chronic watery diarrhea, short bowel syndrome, bowel fistula, acute pancreatitis, continuous nasogastric suctioning, malabsorption steatorrhea, and extensive bowel resection. A rare inborn error of metabolism (primary intestinal hypomagnesemia), characterized by a selective defect in magnesium adsorption, is another known cause. The renal causes include Bartter's and Gitelman's syndromes, postobstructive diuresis, post–acute tubular necrosis, renal transplantation, and interstitial nephropathy.[5-8] Hypomagnesemia may also accompany other disorders, including phosphate depletion, hungry-bone syndrome after parathyroidectomy, correction of chronic systemic acidosis, postobstructive nephropathy, renal transplantation, and the diuretic phase of acute tubular necrosis.[6] Many medications, particularly aminoglycosides, furosemide, and amphotericin-B, can also cause or contribute to magnesium depletion.

Hypomagnesemia is known to produce a wide variety of clinical presentations. Clinically, neuromuscular hyperexcitability may be the first symptom to manifest in individuals with hypomagnesemia. Magnesium deficiency is associated with hypocalcemia and hypokalemia, fatigue, lethargy and apathy, anxiety, insomnia, irritability, weakness, convulsions, delirium and coma, muscle spasm, tremor and tetany, high blood pressure, atherosclerosis, cardiomyopathy, cardiac spasm, cardiac arrhythmias, tachycardia, supraventricular ectopy, sudden cardiac death, insulin resistance, sugar cravings, nerve conduction problems, anorexia, nausea, vomiting, abdominal pains, paralytic ileus, dysmenorrhea, PMS, and poor nail growth.[5,9-12]

Dietary Sources

The magnesium content in foods varies widely, as does the soil content of magnesium. Nuts (almonds, cashews, Brazil), soybeans, brewer's yeast, buckwheat, and wheat bran are rich sources of magnesium, with 200 to 400 mg per 100 g of food.

Moderate sources include corn, peas, carrots, barley, oats, rye, wheat, rice bran, pecans, filberts, pistachios, black walnuts, green leafy vegetables (kale, endive, chard beet tops), celery, alfalfa, figs, apples, lemons, peaches, almonds, whole grains (millet, cornmeal, wheat germ, barley, buckwheat, oats), tahini, sunflower seeds, brown rice, sesame seeds, black-eyed peas, lima beans, tofu, lentils, potato, sweet potato, peas, brussels sprouts, broccoli, cauliflower, avocado, dates, banana, blueberries, grape juice, cantaloupe, orange juice, and milk.

Nutrient Preparations Available

Magnesium citrate, magnesium gluconate, and magnesium lactate are more soluble and bioavailable than magnesium oxide.
Magnesium chloride is more soluble than magnesium oxide, gluconate, citrate, hydroxide, and sulfate and does not require stomach acid for solubility, but its use is limited because of its hygroscopic properties.
Magnesium hydroxide (milk of magnesia).
Magnesium sulfate (Epsom salts).

Dosage Forms Available

Capsule, liquid, powder, spray, tablet, injectable (prescription only), intravenous (inpatient).

Dosage Range

Adult

Dietary: 300 to 400 mg/day (Dietary Reference Intake; DRI)
Pregnant or lactating females: 450 to 550 mg/day (DRI)
Supplemental/Maintenance: 250 to 500 mg/day.
Pharmacological/Therapeutic: 50 to 2500 mg/day; 5 to 6 g have been used under close medical supervision.
Toxic: Single doses of 800 mg may cause diarrhea. Significantly lower doses can be toxic in renally impaired individuals.

Pediatric (< 18 Years)

Dietary: Infants, 0-6 months: 50 mg/day (DRI)
Infants, 7-12 months: 70 mg/day (DRI)
Children, 1-10 years: 150 to 250 mg/day (DRI)
Adolescents, 11-18 years: 300 to 400 mg/day (DRI)
Supplemental/Maintenance: Not established.
Pharmacological/Therapeutic: Not established.
Toxic: Not established.

Laboratory Values

Consensus is lacking as to what constitutes an abnormally low plasma magnesium concentration [Mg^{++}] and how to best assess magnesium depletion in critical tissues. Some authorities contend that measuring serum magnesium concentration and urinary magnesium excretion is usually sufficient in most cases to diagnose magnesium deficiency.[5] However, serum magnesium is a very poor indicator of how much magnesium is actually in the tissues, particularly cardiac tissue, which normally has much higher concentrations of magnesium than typical of serum. Measuring white blood cell (WBC) magnesium may provide a more sensitive indicator of tissue levels. An anionic magnesium measurement, pioneered by Drs. Burton and Bella Altura at Down-State University of New York in Brooklyn, appears to be a considerably more accurate indicator of tissue levels of magnesium than either WBC or red blood cell (RBC) measurements. Koivisto and other researchers at Helsinki University Hospital in Finland assert that spot serum ionized magnesium reveals depletion poorly, and that the most reliable method for evaluating magnesium status is the magnesium loading test. In cases of depletion, uptake of magnesium is increased by 20% to 50%, reaching 6% of normal magnesium status; normally, it represents less than 1% of the TBMg.[13] A recently developed in vitro blood load test using a magnesium-stable isotope appears to offer an accurate assessment of magnesium status, based on initial animal research.[14] Sublingual buccal cell scrapings analyzed with x-ray fluorescence spectroscopy, developed by Burton Silver, have been shown to correlate well with cardiac tissue levels; this is considered the best clinically available test by many magnesium experts.[15]

Urinary Magnesium

Urinary magnesium provides a sensitive measure of magnesium status.
Deficiency: Excretion of less than 1 mmol/day indicates magnesium deficiency.
Leukocyte magnesium levels may reflect tissue levels.
Normal range: 3.0 to 4.0 ±0.09 fmol/cell.

Serum Ionized Magnesium

Serum ionized magnesium is a superior index, compared to serum levels, because the ionized portion of blood magnesium is not affected by variables that alter serum proteins.
Normal range: 0.5 to 0.66 mmol/L.

Serum Magnesium

Serum magnesium is an insensitive index of body magnesium stores; levels fall only with advanced deficiency.
Normal range: 0.75 to 1.05 mmol/L.
Occasionally, parenteral magnesium load test can be used to assess magnesium status.

SAFETY PROFILE

Overview

Magnesium has a very high therapeutic index, and hypermagnesemia is rare and usually iatrogenic, most commonly after intravenous (IV) magnesium, resulting from magnesium-containing laxatives or antacids, or rarely with intramuscular (IM) injection. Magnesium excess and toxicity most often result in diarrhea, drowsiness, weakness, and lethargy but may lead to depression of the central nervous system (CNS) and possibly death. Those most at risk are the elderly and patients with GI disorders or renal insufficiency.[16] Treatment of hypermagnesemia primarily consists of discontinuation of magnesium intake and introduction of calcium administration, but hemodialysis may be necessary in some cases.

Nutrient Adverse Effects

General Adverse Effects

Toxicity from oral ingestion of magnesium supplements is highly improbable in individuals with normal renal function, other than the potential for osmotic diarrhea. Clinical manifestations of hypermagnesemia include hypotension, nausea, vomiting, urinary retention, bradycardia, respiratory

depression, depressed mental status, and electrocardiographic (ECG) abnormalities. Diarrhea is the most common adverse effect from oral magnesium supplements but is not associated with parenteral administration. Excessive oral magnesium intake can actually lead to a magnesium deficiency if it causes chronic diarrhea. Magnesium also competes with calcium and may induce a calcium deficiency if calcium intake levels are already low. About 800 mg of elemental magnesium will generally cause loose stools, but some individuals may tolerate much higher doses. Different forms of magnesium, such as magnesium glycinate, may be tolerated better as well. Slow-release forms of magnesium (e.g., Slo-mag), may be helpful in elevating the intracellular levels of magnesium. Individuals with kidney failure must be cautious about magnesium supplementation because they may experience elevated serum levels with associated toxicity symptoms.

Intravenous magnesium, because of its effect on smooth muscles, may cause hypotension along with dizziness and fainting. It may also cause respiratory depression or depletion of potassium with high doses and rapid infusion.

Intramuscular injections can often be painful and may cause a persistent lump if injection does not go deep enough to reach the muscle tissue. After the magnesium is loaded into the syringe, a small amount of 2% lidocaine can be drawn into the tip of the syringe to ease the reaction.

Adverse Effects Among Specific Populations

Gitelman's syndromes.

Pregnancy and Nursing

No problems have been reported with normal intake during pregnancy and lactation.

Infants and Children

No problems have been reported with normal intake in infants and children.

Contraindications

Individuals with impaired kidney function can accumulate magnesium, which is potentially fatal. Some medications, such as aminoglycosides and amphotericin B, cause both renal tubular damage and magnesium depletion patterns.

Individuals with high-grade atrioventricular blocks or bifascicular blocks must avoid magnesium supplementation because it could slow cardiac conduction.

Precautions and Warnings

Magnesium supplementation may theoretically alter glucose regulation to such a degree as to be problematic for individuals with hypoglycemia or diabetes. Gradual introduction and increase of dosage will generally prevent complications. Close supervision and regular monitoring may be appropriate.

INTERACTIONS REVIEW

Strategic Considerations

Although oral magnesium, as with many minerals, can bind and reduce bioavailability of many medications, the primary interactions of clinical significance derive from depletion and deficiency of this critical nutrient. Dietary magnesium deficiency is relatively common in the modern world, much more than usually expected, and its implications penetrate many aspects of human physiology, with the cardiovascular lesions being the most common arena of adverse effects. Inadequate dietary intake may affect the young and the aged, the poor and the institutionalized, the alcoholic and the malnourished, but iatrogenic causes of magnesium depletion produce many of the most severe outcomes. Clinically significant alterations in serum concentrations of Mg^{++} (and K^{+}) not only are frequently observed in acute or severely ill patients, especially in emergency rooms or intensive care wards, but also are a common adverse effect of many medications. Accurate assessment of magnesium status can be elusive but is critical because many symptoms of magnesium deficiency are nonspecific, and their effective correction requires early detection and intervention. In particular, digitalis and diuretics can intensify an underlying magnesium deficiency, leading to cardiac arrhythmias that are refractory unless magnesium is integrated into the therapeutic regimen. Furthermore, magnesium functions in association with other key minerals in supporting cardiovascular homeostasis, and these nutrients must often be administered in concert. Diuretic-treated hypertensive patients are particularly susceptible to potassium depletion and a resulting increased incidence of ventricular ectopy and sudden death. In such cases, potassium administration alone is inadequate, and concomitant magnesium is essential to intracellular potassium repletion and cardiovascular stabilization. Individuals receiving diuretic therapy, especially those with congestive heart failure, are also prone to chloride loss leading to metabolic alkalosis; this state interferes with potassium repletion, and the combination of potassium, magnesium, and chloride is often appropriate.

Ultimately, the disruptions of magnesium availability and function have their greatest impact on those populations most at risk for their adverse consequences. Furthermore, because the primary adverse effects of magnesium intake occur in individuals with compromised renal function, it is important that kidney function be assessed initially and monitored regularly, along with magnesium status. Importantly, the pharmacokinetic interaction between magnesium and many medications, involving formation of chelated complexes, reduces absorption and bioavailability of both agents. Both the nutrient and the drug presumably play important roles in the therapeutic strategy, so the separation of their administration by 2 to 4 hours avoids the interference and enables both agents to express their full activity.

NUTRIENT-DRUG INTERACTIONS

Albuterol/Salbutamol and Related Beta-2-Adrenoceptor Agonists (Inhalant Bronchodilators)

Evidence: Albuterol (salbutamol; Albuterol Inhaled, Proventil, Ventolin); combination drug: albuterol and ipratropium bromide (Combivent); rimiterol (Pulmadil)

Extrapolated, based on similar properties: Fenoterol (Berotec), isoetharine (Arm-A-Med, Bronkosol, Bronkometer), isoproterenol (isoprenaline; Isuprel, Medihaler-Iso), levalbuterol (Xopenex), metaproterenol (Alupent), pirbuterol (Exirel), rimiterol (Pulmadil), salmeterol (Serevent, Combination drug: Advair), terbutaline (Brethaire, Brethine, Bricanyl), tulobuterol (Brelomax).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:	Evidence Base:
2. Probable	◉ **Emerging**

Effect and Mechanism of Action

Magnesium can enhance the therapeutic efficacy of albuterol, and potentially other adrenergic bronchodilators, as a delivery vehicle, as a concomitant therapy, or simply as nutrient support in the treatment of individuals with asthma. Both agents exercise a bronchodilatory effect that can be amplified by coadministration. Albuterol therapy is associated with significant hypokalemia but apparently does not directly deplete magnesium levels.

Research

Magnesium deficiency is associated with the occurrence and severity of asthma, particularly airway hyperreactivity, wheeze, and impairment of lung function. Hypomagnesemia is common in chronic asthmatic individuals, and those with low serum magnesium tend to have more hospitalizations than chronic asthmatic persons with normal magnesium; hypomagnesemia is also associated with more severe asthma.[17]

Human studies indicate that coadministration of albuterol and magnesium can invoke synergistic effects in the treatment of asthma, but concerns have been raised that adrenergic bronchodilators may adversely affect magnesium (and potassium) levels. Magnesium sulfate is considered an effective bronchodilator in the treatment of acute, moderate to severe asthma when administered intravenously, and it can be safely administered to patients with stable asthma by inhalation.[18-20] However, Lipworth et al.[21] found that inhaled albuterol caused no significant change in magnesium level, but it did produce hypokalemic and hyperglycemic effects of probable clinical significance, especially during acute exacerbations of airflow obstruction.

The therapeutic effects of and supportive interactions between albuterol and magnesium have been researched in various permutations. In vitro experimental data show that magnesium increases beta-receptor affinity to agonists. Clinical research comparing inhaled magnesium sulfate and albuterol (salbutamol sulfate) in the treatment of patients with acute asthma has found that both agents produced significant bronchodilatory effects, but that the duration from the albuterol was longer than that of the magnesium (e.g., 6 hours vs. 1 hour).[22,23] In a randomized, double-blind, controlled trial involving 35 patients with acute asthma, Nannini et al.[24] found that isotonic magnesium sulfate, as a vehicle for nebulized albuterol, increased the peak flow response to treatment compared with salbutamol plus normal saline. In a small, double-blind, placebo-controlled trial involving six patients with asthma, Rolla et al.[25] observed that a mild sustained increase in serum magnesium level, using IV magnesium infusion, increases the bronchodilating effect of low doses of albuterol, possibly through an increased beta-receptor affinity. They found, however, no effect on the maximum bronchodilating effect of albuterol. Subsequently, in a double-blind placebo-controlled trial involving 52 emergency care patients, Hughes et al.[26] demonstrated an enhanced bronchodilator response using isotonic magnesium as an adjuvant to nebulized albuterol in the treatment of severe asthma. The clinical relevance of these findings remains contentious, particularly whether the use of isotonic magnesium confers any additional improvement to optimized nebulized bronchodilator therapy with albuterol and ipratropium, standard first-line therapies for the treatment of acute severe asthma. No clinical trials have yet been published exploring any potential differential clinical response to acute albuterol therapy in individuals regularly supplementing with pharmacologically efficacious doses of magnesium compared with those not taking magnesium regularly for asthma (or other comorbid conditions); clinical trials into such integrative options are warranted.

In 2005 the *Cochrane Review* published a meta-analysis examining the evidence regarding the use of inhaled magnesium sulfate in conjunction with inhaled beta-2 agonists. They concluded that there was good evidence that nebulized magnesium sulfate was safe and effective and that it should be considered as a combined therapy with beta-2 agonists. The authors noted that magnesium sulfate was most useful in situations where the asthmatic exacerbations were severe.[27]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Magnesium can provide an efficacious adjuvant to conventional care for patients with asthma, including coadministration of magnesium sulfate with albuterol in emergency care settings. Concomitant use, especially in acute care and through IV infusion, will inherently be appropriate only under qualified medical care informed by an integrative approach to, and necessary training in, such synergistic therapeutic options. Close monitoring of potassium and magnesium levels, and possible coadministration of either or both, is appropriate when administering beta-2-adrenoceptor agonists, such as albuterol/salbutamol, levalbuterol, and rimiterol, as inhalant bronchodilators or especially as IV infusions. Within conventional practice, bronchodilators are almost never used alone (except for pure exercise-induced bronchospasm), and some treatment directed at airway inflammation, predominantly inhaled corticosteroids, is considered a necessary part of asthma management.

Aminoglycoside Antibiotics

Amikacin (Amikin), gentamicin (G-mycin, Garamycin, Jenamicin), kanamycin (Kantrex), neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin), netilmicin (Netromycin), paromomycin (monomycin; Humatin), streptomycin, tobramycin (AKTob, Nebcin, TOBI, TOBI Solution, TobraDex, Tobrex).

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
2. Probable

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Aminoglycoside antibiotics can induce magnesium depletion and deficiency-related symptoms by several mechanisms. Neomycin impairs absorption of oral magnesium.[28,29] Aminoglycosides can inhibit hormone-stimulated Mg^{++} uptake in distal convoluted tubule cells.[30] Gentamicin can cause increased urinary magnesium loss.[31,32] Renal tubular damage and nonoliguric renal insufficiency are well-known nephrotoxic adverse effects resulting from aminoglycosides, particularly gentamicin and tobramycin, and can lead to hypomagnesemia, usually combined with hypocalcemia, hypokalemia, and alkalosis.[31,34-35] Such tubular damage may occasionally be reversible in the absence of any change in the renal function.[36]

Research

Numerous animal studies have demonstrated hypomagnesemia, as well as hypocalcemia, hypokalemia, and alkalosis, as a result of aminoglycoside-induced renal tubular damage.[30,35,37,38]

Keating et al.[39] reported that 17 oncology patients developed a complex metabolic syndrome of 2 to 8 weeks' duration, characterized by hypocalcemia, hypomagnesemia, and hypokalemia, after administration of several aminoglycoside antibiotics, including tobramycin, gentamicin, amikacin, and sisomicin. The authors attributed these adverse outcomes to the nephrotoxic effects of the aminoglycoside and noted the possible potentiating action of chemotherapeutic agents, particularly doxorubicin. Twelve patients died before recovering from the metabolic stress, and five patients developed progressive renal impairment. Kes and Reiner[31] described renal wasting of magnesium and symptomatic hypomagnesemia, hypocalcemia, and hypokalemia in seven patients after gentamicin therapy. They noted a pattern of "excessive and inappropriate urinary excretion of magnesium and potassium in the presence of subnormal serum concentrations" and suggested that adverse effects were most likely in older patients given large doses of gentamicin over extended periods. Aminoglycosides and platinum together are particularly responsible for tubular damage.

Akbar et al.[40] have noted that hypomagnesemia may be especially common among children with cystic fibrosis who have a history of repeated use of aminoglycosides.

Reports

Kelnar et al.[41] reported the case of a 12-year-old boy who developed renal wasting of magnesium, calcium, and potassium, with secondary hypomagnesemia, hypocalcemia, and hypokalemia (without hyperaldosteronism) after treatment with high-dose gentamicin over 4 months. They recommended that prolonged courses of gentamicin not be administered if less toxic antibiotics are suitable, and that, when it is given, plasma magnesium, calcium, and potassium levels be monitored during and after treatment.

Slayton et al.[42] reported a case of tetany in a child with acquired immunodeficiency syndrome (AIDS) who developed magnesium, calcium, and potassium depletion, requiring prolonged replacement therapy, subsequent to a 3-week course of IV tobramycin. Adams et al.[43] reported hypomagnesemic tetany associated with repeated courses of IV tobramycin in a patient with cystic fibrosis.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing aminoglycosides, particularly on a repeated or chronic basis, should regularly monitor kidney function along with magnesium and potassium status, especially in individuals in high-risk groups, such as children and the elderly. Nutritional support may restore normal levels of magnesium, as well as potassium or other related minerals; prophylactic administration may be appropriate in susceptible populations. Individuals taking neomycin are generally at less risk of adverse effects as a result of magnesium depletion. Clinically significant drug-induced magnesium depletion is an uncommon but important complication of gentamicin therapy. However, in patients receiving IV tobramycin, close monitoring of calcium, magnesium, and potassium levels and the consideration of mineral replacement are especially warranted. Serum creatinine, blood urea nitrogen (BUN), and creatinine clearance should be measured before initiating therapy and monitored throughout treatment. In this regard, many nutritionally oriented practitioners find that testing magnesium levels in RBCs is much more reliable than testing serum magnesium, even though low serum levels virtually always reflect serious intracellular compartment deficits. In individuals with a low threshold for osmotic diarrhea, parenteral magnesium replacement may be the only effective way to replenish the intracellular compartment. Careful assessment should precede administration of magnesium or potassium and then preferably within the context of integrative care involving health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics.

Magnesium supplementation is often medically appropriate to prevent or correct depletion patterns associated with the various aminoglycosides. Even though conclusive evidence demonstrating the unqualified need for therapeutic supplementation is lacking, 250 to 400 mg daily would generally provide a safe, protective dose of magnesium for individuals receiving neomycin for more than 2 to 3 days. Administration of magnesium in the dosage range of 300 to 500 mg daily is usually appropriate for individuals prescribed more potent aminoglycosides but requires evaluation of renal function testing and other individual characteristics. Magnesium augmentation can be risky in patients with compromised renal function and is usually contraindicated in such cases. It is also important to note that magnesium is needed to maintain intracellular potassium, as well as calcium homeostasis, because PTH production is magnesium dependent.

Amphetamines and Related Stimulant Medications

Amphetamine aspartate monohydrate, amphetamine sulfate, dextroamphetamine saccharate, dextroamphetamine sulfate; D-amphetamine, Dexedrine.
Methylphenidate (Metadate, Methylin, Ritalin, Ritalin-SR; Concerta).
Combination drug: Mixed amphetamines: amphetamine and dextroamphetamine (Adderall; dexamphetamine).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
3. Possible

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Magnesium may favorably alter the kinetics of mixed amphetamines and thereby enhance their retention and bioavailability. Medications in this class appear to elevate plasma magnesium levels and favorably shift the calcium/magnesium ratio. Further, the independent therapeutic effects of both agents on various forms of hyperactivity may result in an additive or synergistic effect, pharmacological and/or functional.

Research

Magnesium salts, specifically magnesium hydroxide in the context of antacids, alter the pharmacokinetics of amphetamines so as to enhance retention of such medications, thereby increasing their activity.[44] Conversely, in a double-blind placebo-controlled study of methylphenidate and dextroamphetamine in hyperactive boys, Schmidt et al.[45] found that plasma magnesium levels were significantly higher and calcium/magnesium ratio was significantly lower after 3 weeks of dextroamphetamine treatment, compared with the baseline or placebo condition. These authors cited other research suggesting that concomitant magnesium may enhance learning and the therapeutic response to stimulants. In particular, they proposed that the lowering of the calcium/magnesium ratio may play a significant role in the therapeutic action of stimulants such as dextroamphetamine.

The significant association observed between magnesium deficiency and hyperactivity has led to promising research

into the role of magnesium as a component of an integrative approach to the treatment of this cluster of conditions.[46] Starobrat-Hermelin and Kozielec[47] assessed magnesium levels (in blood serum, RBCs, and hair) in 116 children with recognized attention deficit–hyperactivity disorder (ADHD) and determined that 95% demonstrated some form of magnesium deficiency, most frequently in hair (77.6%), RBCs (58.6%), and blood serum (33.6%). Subsequently, this same research team conducted a clinical trial in which they administered 200 mg/day magnesium to 50 of these children, who had been diagnosed with both ADHD and magnesium deficiency, but not to 25 similarly diagnosed controls. They concluded that the children treated with magnesium, independently of other mental disorders coexisting with hyperactivity, demonstrated an increase in magnesium contents in hair and a significant decrease of hyperactivity, compared with their clinical state before magnesium administration and with the control group.[48] These findings suggest that coadministration of magnesium and mixed amphetamines might produce beneficial clinical outcomes, and that controlled clinical trials into such integrative options is warranted.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing mixed amphetamines can reasonably suggest the option of concomitant magnesium. Given the potential effect on pharmacokinetics, close supervision and regular monitoring are advised, and reduction of the medication dosage may be appropriate if magnesium enhances bioavailability. Coordinated treatment involving health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics may serve to ensure safety and enhance clinical outcomes. A dosage of magnesium in the range of 200 to 400 mg per day, depending on age, weight, diet, and comorbid conditions, would typically be appropriate.

Amphotericin B

Amphotericin B (AMB; Fungizone).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Renal toxicity is a common and serious adverse effect of conventional amphotericin B. Renal impairment manifests as a decrease in glomerular filtration and damage to tubular function.[49] Hypomagnesemia due to renal magnesium wasting can result from cumulative dosages of amphotericin B, most likely from a tubular defect in magnesium reabsorption.[50] Hydration and administration of depleted nutrients, particularly magnesium and potassium, may prevent or reduce such adverse effects.

Research

Barton et al.[50] documented the effect of amphotericin B on magnesium metabolism in 10 adults being treated for systemic fungal infections. After relatively small cumulative dosages of amphotericin B, renal magnesium wasting (as evidenced by fractional magnesium excretion and serum magnesium level) and mild to moderate hypomagnesemia appeared to manifest by the second week of therapy, peak by the fourth week, and then plateau. Follow-up data in three subjects, from 1 year after discontinuation of amphotericin B therapy, showed that serum magnesium level and fractional magnesium excretion were restored to pretreatment levels and indicate that the magnesium wasting was reversible.

Mayer et al.[49] tested the hypothesis that administration of potassium and magnesium corresponding to the amounts lost by the kidneys, as well as sufficient hydration, are necessary to prevent renal function damage. In subsequent clinical trials, they found that the nephrotoxicity of amphotericin B therapy can be significantly reduced through minimal nephroprotective measures, including hydration and administration of magnesium and other ionic minerals susceptible to depletion.[51,52]

Because of the toxicity of amphotericin B, a modified lipid complex variant of the drug was introduced. The liposomal amphotericin B formulation appears to be well tolerated and effective in treating systemic fungal infections, without the high occurrence of severe adverse effects associated with conventional amphotericin B therapy.[53-55]

Reports

Clinicians have published case reports of tetany and other adverse effects of hypomagnesemia and hypokalemia caused by IV administration of amphotericin B.[56-58]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing extended courses of amphotericin B may find it prudent to recommend magnesium administration (e.g., IV or 300 mg/day orally). Monitoring of magnesium levels and compensatory administration may be especially appropriate in patients with cardiovascular conditions or pathophysiological dysfunction in whom magnesium depletion might have clinically significant impact. Vigorous hydration and IV administration of magnesium, potassium, and sodium, as described by Mayer and Doubek, in the context of close monitoring of renal function and magnesium and other ionic levels, are appropriate for inpatient or oncological care settings where IV amphotericin B is being administered for systemic fungal infections. Use of the liposomal form of amphotericin B may reduce risk of adverse effects and complications.

Bisphosphonates

Evidence: Alendronate (Fosamax), risedronate (Actonel), tiludronate (Skelid).
Extrapolated, based on similar properties: Clodronate (Bonefos, Ostac), etidronate (Didronel).
Related but evidence against extrapolation: Pamidronate (Aredia), zoledronic acid (Zometa).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Some oral magnesium compounds may interfere with the absorption and bioavailability of the various bisphosphonate

derivatives. Magnesium salts may interfere with absorption of tiludronate. This pharmacokinetic interaction typically is immediate in onset but of moderate severity. According to manufacturers, simultaneous ingestion of divalent cations will interfere with absorption of the various bisphosphonates by forming insoluble (nonabsorbable) chelates; specifically, the bioavailability of tiludronate is reduced 60% by supplements or antacids containing magnesium (or aluminum) and 80% by calcium.

The occurrence of insoluble chelates will also reduce the bioavailability of the magnesium and interfere with its therapeutic efficacy.

Research

The apparently unpublished research cited by the manufacturers of these agents and secondary references primarily focuses on magnesium in the context of antacids. However, the various extrapolations underlying the cautions are reasonable and consistent with generally accepted pharmacological research and principles regarding chelation properties of orally administered minerals.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

In patients undergoing therapy with bisphosphonates, concurrent but segregated administration of magnesium (and calcium) enables an integrative approach to therapeutics. Oral magnesium, as well as other mineral supplements or related antacids, should be taken at least 2 hours before or 30 minutes after oral administration of bisphosphonate derivatives to minimize interference with the drug's absorption. Conversely, patients taking magnesium for therapeutic purposes will derive greater benefit from the nutrient by avoiding its binding with the bisphosphonate agent.

Calcium Channel Blockers

Evidence: Felodipine (Plendil), nifedipine (Adalat, Adalat CC, Nifedical XL, Procardia, Procardia XL).
Extrapolated, based on similar properties: Amlodipine (Norvasc); combination drug: amlodipine and benazepril (Lotrel); bepridil (Bapadin, Vascor), diltiazem (Cardizem, Cardizem CD, Cardizem SR, Cartia XT, Dilacor XR, Diltia XT, Tiamate, Tiazac); felodipine combination drugs: felodipine and enalapril (Lexxel), felodipine and ramipril (Triapin); gallopamil (D600), isradipine (DynaCirc, DynaCirc CR), lercanidipine (Zanidip), nicardipine (Cardene, Cardene I.V., Cardene SR); nifedipine combination drug: nifedipine and atenolol (Beta-Adalat, Tenif); nimodipine (Nimotop), nisoldipine (Sular), nitrendipine (Cardif, Nitrepin), verapamil (Calan, Calan SR, Covera-HS, Isoptin, Isoptin SR, Verelan, Verelan PM); combination drug: verapamil and trandolapril (Tarka).

Interaction Type and Significance

- ⊕✗ **Bimodal or Variable Interaction, with Professional Management**
- ✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**
- ✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**
- ≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **3. Possible**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Both calcium channel blockers and magnesium can reduce the amount of ionic calcium available to muscle cells. Their concomitant use can result in an additive effect, thereby enhancing their hypotensive effect and decreasing cardiac function. Felodipine therapy is also associated with increased magnesium excretion.

Research

Magnesium's central role in regulating calcium metabolism contributes to its ability to lower blood pressure[59] and may account for its reputed efficacy in the treatment of glaucoma.[60] Both calcium channel blockers and magnesium are used to treat a range of cardiovascular conditions, especially arrhythmias and angina, and individuals with such conditions (e.g., variant angina)[61] often demonstrate magnesium deficiency. In a rodent study, Mervaala et al.[62] found that the cardiovascular effects of low-dose felodipine and ramipril could be enhanced by regular administration of a magnesium-enriched salt, in place of sodium. However, Davis et al.[63] reported that the synergistic effect from combining magnesium sulfate and calcium channel blockers may decrease cardiac function and increase the risk of cardiac toxicity in pregnant women.

Reports

Two published case reports have described the development of muscular weakness and subsequent paralysis in pregnant women who were being treated for preeclampsia with concomitant oral nifedipine and IV magnesium sulfate.[64,65] In one case, cessation of the magnesium resulted in the resolution of the adverse symptoms within 25 minutes. In the other case, the paralytic state reversed after IV administration of calcium gluconate. Waisman et al.[66] reported a potentiation effect in two pregnant patients who were receiving methyldopa and IV magnesium and developed transient hypotension within 1 hour after administration of oral nifedipine.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The concomitant use of calcium channel blockers and magnesium can produce an additive effect that has the potential to be detrimental or beneficial, depending on patient characteristics, pathophysiological processes, and clinical management. Initial evaluation and regular monitoring of magnesium (and potassium) levels are necessary when the patient's history and cardiac risk factors indicate that magnesium might be clinically appropriate as part of the therapeutic strategy, as well as to counter drug-induced magnesium depletion. In particular, both magnesium and calcium channel blockers may have roles to play in the prevention and treatment of hypertension during pregnancy, especially preeclampsia, but their concomitant use should be discouraged except under close supervision and regular monitoring. The coordinated use of a calcium channel blocker and oral magnesium may provide greater efficacy while allowing reduced dosage of the drug and reducing the risk of adverse effects. However, collaboration by health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics is essential given the potential synergy of these combined agents and attendant risks. In most cases the typical therapeutic dosages of magnesium for adults are in the range of 250 to 350 mg per day.

Cisplatin

Cisplatin (*cis*-Diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ).

Interaction Type and Significance
≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**
◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable**
Evidence Base: ● **Consensus**

Effect and Mechanism of Action
Cisplatin can induce clinically significant hypomagnesemia by increasing urinary excretion of magnesium, through its toxic effects on the kidneys, and possibly by a direct injury to mechanisms of magnesium reabsorption in the ascending limb of Henle's loop as well as the distal tubule.[67-70] This drug-induced impairment of the renal tubules' ability to conserve magnesium may persist for months, or possibly years, after discontinuing the drug.[71] Cisplatin may also cause excessive excretion of potassium that will amplify the adverse effects of magnesium depletion, and vice versa.[72,73]

Research
Numerous animal and human studies, as previously cited, have documented the occurrence, mechanisms, and sequelae of cisplatin's nephrotoxic effects on magnesium (and potassium) status. One British study found higher serum magnesium concentration levels in children given IV magnesium before and after administration of cisplatin than in those give magnesium only after the cisplatin.[74] These researchers concluded that magnesium supplements should be given to patients receiving cisplatin during the precisplatin hydration period to prevent hypomagnesemia. An unrecognized and untreated magnesium deficiency can lead to refractory potassium depletion. Rodriguez et al.[75] and Whang et al.[76] documented cases of refractory hypokalemia following cisplatin therapy that failed to respond to potassium administration until hypomagnesemia was recognized and corrected.

Reports
Van de Loosdrecht et al.[76] reported the case of seizures in a male patient with disseminated testicular cancer caused by cisplatin-induced hypomagnesemia.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Physicians prescribing or administering cisplatin are advised to evaluate magnesium and potassium status, as well as renal function, before initiating therapy and throughout its course; some clinicians would recommend continuing such monitoring through posttherapy follow-up examinations. The research cited suggests that coadministration of magnesium be initiated before beginning chemotherapy and that supplemental potassium be added if indicated. A collaborative approach based on principles of integrative care and involving health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics is recommended to enhance safety and efficacy.

Colchicine

Colchicine

Interaction Type and Significance
≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **4. Plausible**
Evidence Base: ☐ **Inadequate**

Effect and Mechanism of Action
Colchicine has been linked to impaired absorption of magnesium.[77]

Research
Published research has documented colchicine-induced depletion of calcium, potassium, and other nutrients and reported that such absorption-related depletion patterns resolved subsequent to cessation of colchicine therapy. Clinical trials investigating and confirming specific effects by colchicine on magnesium are lacking.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Individuals prescribed colchicine would most likely benefit from daily supplementation with a high-potency multivitamin/mineral formulation to compensate for these interactions. Separate oral intake by at least 2 hours.

Corticosteroids, Oral

Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol) prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).
Similar properties but evidence indicating no or reduced interaction effects: Inhaled or topical corticosteroids.

Interaction Type and Significance
≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**
◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable**
Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action
Long-term use of corticosteroids is associated with depletion of magnesium and decrease in serum and bone levels.[22,78,79] Magnesium deficiency adversely influences calcium and vitamin D metabolism and is primarily associated with hypocalcemia[80]; bone loss is a significant adverse effect of long-term steroid therapy.

Magnesium trisilicate has been reported to interfere with GI absorption of dexamethasone in healthy male volunteers, as indicated by the increased urinary excretion of 11-hydroxycorticosteroids.[81] However, magnesium trisilicate is a poorly absorbable form of magnesium never used as a nutrient source, although sometimes used in laxative preparations.

Research
Using adult male rats, Simeckova et al.[78] found that prednisolone caused a significant decrease in bone magnesium content. In a clinical trial involving 95 patients with chronic airway obstruction, Rolla et al.[22] found a significant negative correlation between serum magnesium and the length of oral steroid therapy; diuretics were also associated with a significantly lower serum magnesium level. Atkinson et al.[79] conducted a clinical trial involving 56 children with acute lymphoblastic leukemia (ALL) to investigate abnormalities in mineral homeostasis and

bone mass. They found that more than 70% of children had abnormally low plasma 1,25-dihydroxyvitamin D, 73% had low osteocalcin (a reflection of vitamin K status), and 64% had hypercalciuria, at diagnosis, indicating an effect of the leukemic process on vitamin D metabolism and bone turnover. During remission induction, treatment with high-dose steroid (prednisone or dexamethasone) resulted in further reduction in plasma osteocalcin and elevated PTH levels. Despite normal dietary intake and absorption of magnesium, 84% of children developed hypomagnesemia (of whom 52% were hypermagnesuric) by 6 months; plasma 1,25-dihydroxyvitamin D remained abnormally low in 70%. The authors attributed the altered magnesium status to renal wasting of magnesium after cyclical prednisone therapy and treatment with aminoglycoside antibiotics. Magnesium coadministration for up to 16 to 20 weeks normalized plasma magnesium in only half the children treated for hypomagnesemia.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Magnesium can provide an important therapeutic component within integrative care for many pathological and dysfunctional conditions, such as asthma and irritable bowel syndrome, which are often treated with corticosteroids. Physicians prescribing oral corticosteroids for longer than 2 weeks should discuss with their patient the potential benefit of concomitant magnesium to counter the depleting effects of the drug(s). A typical dose in such situations would be 300 to 400 mg of magnesium daily. A multimineral formulation would add support against parallel depletions of other vulnerable minerals; however, clinically effective levels of potassium require a prescription. Any such mineral preparations should be taken at least 2 hours before or 30 minutes after oral corticosteroids to minimize risk of interference with absorption of the medication.

Cyclosporine

Cyclosporine (Ciclosporin, cyclosporin A, CsA; Neoral, Sandimmune, SangCya).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:
1. Certain

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Cyclosporin A (cyclosporine) is a highly potent immunosuppressive agent for solid-organ transplantation, but its use carries significant risk of varied adverse effects. In addition to magnesium depletion and its sequelae, cyclosporine's adverse effects include nephrotoxicity, hepatotoxicity, hypertension, neurotoxicity, and gum hyperplasia.[82] Magnesium may reduce the severity of some of the drug's toxic effects, especially its nephrotoxicity.

Severe hypomagnesemia and renal magnesium wasting are associated with the use of cyclosporine and many of its toxic effects. In particular, systemic depletion of magnesium appears to play a significant role in the pathogenesis of cyclosporine-induced neurotoxicity and produces a high risk of seizures.[82-94]

Research

Pere et al.[95] reported beneficial effects of dietary magnesium and potassium on cardiac and renal morphological features in cyclosporin A–induced damage in spontaneously hypertensive rats. In a series of rodent studies, Asai et al.[96] showed that correction of cyclosporine-induced hypomagnesemia by magnesium coadministration ameliorates chronic cyclosporin A (CsA) nephropathy by inhibiting gene expression of fibrogenic molecules. Subsequently, they demonstrated that CsA induced a decline in glomerular filtration with characteristic striped fibrosis, but that magnesium abolished precedent interstitial inflammation, possibly through inhibition of chemoattractant expression and consequently, attenuated tubulointerstitial fibrosis.[97]

Thompson and June and colleagues documented association between cyclosporine neurotoxicity and hypomagnesemia[83] and the correlation of hypomagnesemia with the onset of cyclosporine-associated hypertension[85] in marrow transplant patients. These researchers concluded that their findings suggested that such adverse effects may be prevented with or treated by magnesium replacement.

Vannini et al.[90] investigated kidney function and magnesium status in 109 renal transplant patients receiving cyclosporine, with allografts functioning stably for more than 6 months and plasma creatinine levels of less than 200 μmol/L, as well as 15 renal transplant patients not receiving cyclosporine and 21 healthy volunteers. They found that the cyclosporine patients showed significantly lower total and ionized circulating magnesium values than the two control groups, and that these deficiencies appeared to be permanent. They also noted that plasma total and ionized magnesium levels were significantly lower among cyclosporine patients treated concurrently with insulin or oral hypoglycemic agents.

Low total serum magnesium concentration has been reported in transplant recipients on cyclosporine therapy, and this is a risk factor for hypertension and cardiac death, especially after renal transplant. In a study involving 31 post–renal transplant patients, Thakur et al.[94] found that mean total serum magnesium in posttransplant patients was significantly lower than in 16 chronic renal failure patients who had not yet received a transplant as controls, and that an inverse correlation existed between total serum magnesium and blood CsA concentration. Systolic and diastolic blood pressures were also higher in the cyclosporine-treated patients.

Reports

Numerous published case reports have described aspects of cyclosporine-associated neurotoxicity in recipients of solid-organ and bone marrow transplants, especially in relation to magnesium wasting. Ozkaya et al.[98] reported a case of a 16-year-old renal transplant patient who developed tremor, tinnitus, and peripheral facial paralysis during oral CsA treatment; her serum magnesium level was below the normal range. Al-Rasheed et al.[99] reported on a girl who had idiopathic renal magnesium wasting secondary to suspected Gitelman's syndrome and CsA neurotoxicity after a heart transplant. The child had acute progressive encephalopathy, intractable seizures, quadriparesis, and extensive bilateral cortical involvement on neuroimaging. Many of these symptoms improved dramatically 2 days after discontinuing CsA, and she was fully ambulatory after 6 weeks. This drug-induced neurotoxicity was exacerbated by hypomagnesemia. The authors emphasized that caution was especially important in administering cyclosporine to transplant patients with Gitelman's syndrome or other

acquired magnesium homeostasis disorders because of the possible increased risk of neurotoxicity.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Magnesium coadministration prevents magnesium deficiency and subsequent neurotoxicity resulting from CsA; it may also reduce the severity of nephrotoxicity. In the event of cyclosporine-induced depletion, the prescribing physician should be consulted before any form of magnesium administration is initiated. Renal function testing is advised at baseline and at 6-month intervals, through creatinine clearance and albumin excretion, along with assessment of markers NAG and ALP (D-glucosaminidase and alkaline phosphatase, respectively) for tubular toxicity. Furthermore, initial evaluation and regular monitoring of magnesium levels are necessary in individuals undergoing cyclosporine therapy. Nutritionally oriented physicians generally find that monitoring RBC magnesium levels, rather than serum magnesium, is a more accurate method for diagnosing a deficiency.

Digoxin and Related Cardiac Glycosides

Evidence: Digoxin (Digitek, Lanoxin, Lanoxicaps, purgoxin). Extrapolated, based on similar properties: Deslanoside (cedilanin-D), digitoxin (Cystodigin), ouabain (g-strophanthin).

Nutrient Depletion

Probability: **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Digoxin decreases intracellular magnesium and causes increased urinary magnesium loss. Hypomagnesemia may predispose to digitalis toxicity.

Oral magnesium compounds may interfere with digoxin absorption and bioavailability. Conversely, the occurrence of insoluble chelates will also reduce the bioavailability for the magnesium and interfere with its therapeutic efficacy.

Research

Digoxin decreases intracellular magnesium and reabsorption of magnesium from the kidneys, causing increased urinary magnesium loss, and digitalis (and diuretics) can intensify an underlying magnesium deficiency.[5,100-103] Magnesium deficiencies induced by concomitant diuretic use are especially common in individuals prescribed digoxin.[104,105] Adequate magnesium concentration enhances digoxin's antiarrhythmic activity, particularly by diminishing ventricular response during atrial fibrillation. However, hypomagnesemia inhibits the therapeutic efficacy of digoxin in controlling atrial fibrillation and can increase the risk of cardiac glycoside toxicity, particularly refractory arrhythmias.[75,106-108] Magnesium is also necessary to intracellular potassium repletion in diuretic-treated hypertensive patients.

Magnesium intake, particularly in the form of antacids such as magnesium trisilicate, may result in adsorption of digoxin, reduced absorption in the GI tract, and decreased bioavailibility,[109] although most likely only to a negligible degree.[110-112] In single-dose studies with 10 healthy volunteers, Brown and Juhl[109] found that antacids containing magnesium hydroxide, and particularly magnesium trisilicate, substantially reduced digoxin absorption, apparently through physical adsorption of digoxin by the antacids in the GI tract. However, subsequent research by D'Arcy and McElnay[112] determined that magnesium trisilicate did not significantly interfere with digoxin absorption. Using an in vitro model, previously proven to correlate well with absorption across a physiological membrane in vivo,[110] research by McElnay et al.[111] suggests that magnesium carbonate only weakly impairs digoxin absorption. Overall, research findings are inconclusive.

Reports

Kinlay and Buckley[113] described a patient with digoxin toxicity, associated with ventricular tachycardia, who achieved a more stable junctional rhythm after IV magnesium sulfate (two doses of 10 mmol).

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Digoxin and magnesium both play important therapeutic roles in the treatment of heart failure and related conditions. Normal magnesium levels need to be maintained during digoxin treatment. Given that individuals taking digoxin are especially likely to demonstrate hypomagnesia, supervised nutrient support can be even more important. Hypomagnesemia is known to produce a wide variety of clinical presentations, including neuromuscular irritability, cardiac arrhythmias, and increased sensitivity to digoxin.

Many physicians are aware of the need to monitor and prescribe for potassium depletion but do not consider the issue of magnesium deficiency unless serum levels fall below acceptable levels. Furthermore, many physicians experienced in nutritional assessment consider serum magnesium to be a very poor indicator of how much magnesium is actually in the intracellular compartment. Serum magnesium concentration is maintained within a narrow range by the kidney and small intestine; under conditions of magnesium deprivation, both organs increase their fractional absorption of magnesium. If magnesium depletion continues, the bone store contributes by exchanging part of its content with extracellular fluid. The serum [Mg^{++}] can be normal in the presence of intracellular Mg^{++} depletion, and the occurrence of a low level usually indicates significant magnesium deficiency. Hypomagnesemia is frequently encountered in hospitalized patients and most often in those admitted to intensive care units. The detection of magnesium deficiency can be increased by monitoring RBC magnesium levels, measuring [Mg^{++}] in the urine, or using the parenteral magnesium load test. Assessment of magnesium status may be appropriate but is often not essential since deficiency status is not required for patients to benefit from magnesium administration. However, renal function testing is advisable before initiating such treatment because increased magnesium intake can carry significant risks in patients with renal insufficiency and is usually contraindicated in such cases.

Physicians prescribing digoxin should discuss with their patient the potential benefit of concomitant magnesium as part of a program of integrative care and to counter the depleting effects of the medication. A typical dose in such situations

would be 300 to 500 mg of magnesium daily, depending on the individual's diet, age, genetic predisposition, medications, and other factors. Refractory hypokalemia and hypocalcemia can be caused by concomitant hypomagnesemia and can potentially be corrected with magnesium therapy.[80,104] A multimineral formulation would add support against parallel depletions of other vulnerable minerals. To avoid potential interference with digoxin absorption, mineral preparations should be taken at least 2 hours before or after digoxin. Clinical care within an integrative setting might also emphasize a diet rich in minerals, vitamins, and antioxidants and incorporate fish oil, hawthorn (*Crataegus oxyacantha*), L-carnitine, coenzyme Q10, and other nutrients as part of an evolving and individualized approach to cardiovascular therapeutics.

Diuretics: Loop Diuretics and Thiazide Diuretics

Loop diuretics: Bumetanide (Bumex), ethacrynic acid (Edecrin), furosemide (Lasix), torsemide (Demadex).

Thiazide diuretics: Bendroflumethiazide (bendrofluazide; Naturetin); combination drug: bendrofluazide and propranolol (Inderex); benzthiazide (Exna), chlorothiazide (Diuril), chlorthalidone (Hygroton); cyclopenthiazide (Navidrex); combination drug: cyclopenthiazide and oxprenolol hydrochloride (Trasidrex); hydrochlorothiazide (Aquazide, Esidrix, Ezide, Hydrocot, HydroDiuril, Microzide, Oretic); combination drugs: hydrochlorothiazide and amiloride (Moduretic); hydrochlorothiazide and captopril (Acezide, Capto-Co, Captozide, Co-Zidocapt); hydrochlorothiazide and enalapril (Vaseretic); hydrochlorothiazide and lisinopril (Prinzide, Zestoretic); hydrochlorothiazide and losartan (Hyzaar); hydrochlorothiazide and metoprolol (Lopressor HCT); hydrochlorothiazide and spironolactone (Aldactazide); hydrochlorothiazide and triamterene (Dyazide, Maxzide); hydroflumethiazide (Diucardin), methyclothiazide (Enduron), metolazone (Zaroxolyn, Mykrox), polythiazide (Renese), quinethazone (Hydromox), trichlormethiazide (Naqua).

Probability: **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Loop and thiazide diuretics, to varying degrees, inhibit passive magnesium absorption and increase urinary excretion of magnesium, as well as sodium and potassium, and usually deplete blood levels of magnesium.[5,114-121] In turn, the drug-induced magnesium deficiency can contribute to further potassium depletion. Furthermore, hypokalemia reduces magnesium transport in the distal tubule, increasing urinary magnesium excretion.[122] Ultimately, the relationship between these two patterns of depletion can be difficult to determine, and practically, they need to be treated together in most patients.[73,101,104,105] Although loop and thiazide diuretics inhibit Mg^{++} reabsorption, the tendency to hypomagnesemia may be moderated because of increased proximal tubular reabsorption of Mg^{++} induced by the volume depletion.[6]

Research

Diuretics are generally prescribed to individuals with congestive heart failure (CHF) and other conditions typically associated with hypomagnesemia and other electrolyte imbalances that may increase myocardial electrical instability, as well as risk of malignant arrhythmias and sudden death.[123-126] In particular, hypomagnesemia and hypokalemia occur in a high percentage of patients receiving thiazide monotherapy.[127] Generally, potassium depletion in diuretic-treated hypertensive patients has been linked to an increased incidence of ventricular ectopy and sudden death. In such cases, potassium alone is generally inadequate, and concomitant magnesium administration is required to reestablish intracellular potassium repletion.[73,105] The associated tendency of patients receiving diuretic therapy, especially those with CHF, to chloride loss and subsequent metabolic alkalosis also interferes with potassium repletion. Consequently, the combination of magnesium and potassium (and possibly chloride) is often appropriate.[128]

The extent of magnesium depletion inherently depends on the interaction between the patient's individual physiology and the pharmacological characteristics of the particular diuretic, its drug class, dosage, duration of therapy, and other factors.[129] Furthermore, the time frame of symptom manifestation can vary significantly since extended drug-induced depletion may cause magnesium recruitment from bones to sustain blood levels; tissue levels may be profoundly depleted, even though serum levels are still normal such that low serum levels usually suggest a significant or severe deficiency status.[5,130] Magnesium depletion and hypomagnesemia are common among furosemide-treated patients with chronic CHF. Cohen et al.[131] analyzed clinical, biochemical, and ECG variables relating to serum magnesium aberrations and outcomes in 404 consecutive patients diagnosed with CHF and previously treated with furosemide for at least 3 months. Hypomagnesemia was found in 50 patients (12.3%) and ultimately, after adjustment for renal failure, old age, and severity of CHF, emerged as being significantly associated with shorter survival.

Individuals with Gitelman's syndrome, associated with hypocalciuria and a defect in the gene encoding for the thiazide-sensitive Na^+/Cl^- cotransporter, are particularly at risk for hypomagnesemia and hypokalemia caused by primary renal tubular Mg^{++} wasting.[6-8]

Dorup et al.[132] examined 76 consecutive patients receiving diuretic therapy for 1 to 17 years for arterial hypertension or CHF and found that muscle concentrations of magnesium, potassium, and sodium-potassium pumps were significantly reduced compared with matched controls. When 36 patients with depleted muscle magnesium and/or potassium levels were subsequently given oral magnesium hydroxide for 2 to 12 weeks or 26 weeks, magnesium muscle parameters initially increased, but muscle concentrations of magnesium, potassium, and sodium-potassium pumps did not normalize, in most cases, until after 26 weeks of magnesium administration. Thus, the authors concluded that at least 6 months of oral magnesium therapy appeared to be necessary to restore diuretic-induced disturbances in the concentrations of magnesium, potassium, and sodium-potassium pumps in skeletal muscle.[132]

Ruml and Pak[128] investigated the effect of potassium magnesium citrate, magnesium citrate, and potassium citrate on thiazide-induced hypokalemia and magnesium loss in 62 healthy subjects. They found that all three mineral compounds increased serum potassium concentration compared with that resulting from thiazide alone, and that potassium magnesium citrate and potassium citrate, but not magnesium

citrate, significantly increased urinary pH and citrate values. They concluded that potassium magnesium citrate not only corrects thiazide-induced hypokalemia, but also may avert magnesium loss while providing an alkali load. In a related trial, Ruml et al.[133] tested the efficacy of three different dosages of a potassium and magnesium combination, including up to 800 mg/day of magnesium, and found that four tablets daily (24 mEq potassium, 12 mEq magnesium, 36 mEq citrate) was adequate to overcome hypokalemia and magnesium loss induced by thiazide (50 mg/day) and increased urinary pH and citrate. Likewise, after administering oral magnesium citrate (300 mg daily for 30 days) to 10 patients with severe CHF maintained on high-dose furosemide, Cohen et al.[134] observed a significant increase in peripheral blood mononuclear cell magnesium content and serum potassium levels, whereas the other related parameters remained unchanged.

Parallel attempts at addressing the depleting effects of diuretics have not been as straightforward or as effective as mineral supplementation. Triamterene, a potassium-sparing diuretic, has sometimes been combined with hydrochlorothiazide as a means of mitigating potassium and hydrogen loss. Although often effective at partly compensating for the kaliuretic effect of hydrochlorothiazide, many diabetic patients thus treated either remained or became hypokalemic.[135] However, sometimes the combination of hydrochlorothiazide and lisinopril, an angiotensin-converting enzyme (ACE) inhibitor, has been found to be effective in attenuating thiazide-induced potassium loss, thereby reducing magnesium wasting, because of lisinopril's ability to reduce production of aldosterone. Likewise, in some cases a magnesium-potassium-sparing diuretic such as amiloride (e.g., 5-10 mg) may negate the potassium-wasting effect of 40 mg furosemide.[5] However, Dorup[129] reported that such a furosemide-amiloride combination still produced hypomagnesemia in 12% of those thus treated. Importantly, the combined use of magnesium supplementation and potassium-sparing diuretic(s) could theoretically introduce a risk of hypermagnesemia, although the likelihood of this seems unlikely with normal renal function and oral supplementation.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

In practice, it is generally advisable to coadminister both potassium and magnesium when prescribing any potassium-depleting diuretic, except in those with renal insufficiency. Severe magnesium deficiency may require IM or IV magnesium sulfate or chloride to achieve rapid correction. For long-term care, administration of magnesium at 300 to 600 mg daily is usually appropriate, depending on the individual's diet, age, genetic predisposition, and medications and other factors. Magnesium deficiency status can be evaluated by monitoring RBC magnesium levels, measuring $[Mg^{++}]$ in the urine, using x-ray spectroscopy of sublingual cell scrapings, or using the parenteral magnesium load test. Assessment of magnesium status may be appropriate but is often not essential because deficiency status is not required for patients to benefit from magnesium administration. However, since magnesium augmentation can be risky, and is usually contraindicated, in patients with renal insufficiency, kidney function tests are critical before initiating, and periodically during, concomitant repletion therapy.

As indicated by research findings, concomitant magnesium needs to be maintained for 6 months to compensate for any drug-induced tissue depletion pattern and during and possibly after relevant diuretic therapy. A typical dose for most individuals would be 300 to 500 mg of magnesium daily. A multimineral formulation would add support against parallel depletions of other vulnerable minerals. In the event that diarrhea appears during magnesium administration, switching to magnesium gluconate or glycinate may alleviate this adverse effect. Beyond magnesium and potassium, clinical care within an integrative setting might also emphasize a diet rich in minerals, vitamins, and antioxidants and incorporate dandelion (*Taraxacum officinale*, as a mineral-rich nutritive diuretic), essential fatty acids, coenzyme Q10, calcium, and other elements as part of an evolving and individualized approach to cardiovascular therapeutics involving health care professionals trained and experienced in multiple therapeutic disciplines.

ESTROGENS AND ESTROGEN-PROGESTIN COMBINATIONS

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCept 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).

Hormone Replacement Therapy (HRT): Estrogen-Containing and Synthetic Estrogen and Progesterone Analog Medications

HRT, estrogens: Chlorotrianisene (Tace); conjugated equine estrogens (Premarin); conjugated synthetic estrogens (Cenestin); dienestrol (Ortho Dienestrol); esterified estrogens (Estratab, Menest, Neo-Estrone); estradiol, topical/transdermal/ring (Alora Transdermal, Climara Transdermal, Estrace, Estradot, Estring FemPatch, Vivelle-Dot, Vivelle Transdermal); estradiol cypionate (Dep-Gynogen, Depo-Estradiol, Depogen, Dura-Estrin, Estra-D, Estro-Cyp, Estroject-LA, Estronol-LA); estradiol hemihydrate (Estreva, Vagifem); estradiol valerate (Delestrogen, Estra-L 40, Gynogen L.A. 20, Progynova, Valergen 20); estrone (Aquest, Estragyn 5, Estro-A, Estrone '5', Kestrone-5); estropipate (Ogen, Ortho-Est); ethinyl estradiol (Estinyl, Gynodiol, Lynoral).
HRT, estrogen/progestin combinations: Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); conjugated equine estrogens and norgestrel (Prempak-C); estradiol and dydrogesterone (Femoston); estradiol and norethindrone, patch (CombiPatch); estradiol and norethindrone/norethisterone, oral (Activella, Climagest, Climesse, FemHRT, Trisequens); estradiol valerate and cyproterone acetate (Climens); estradiol valerate and norgestrel (Progyluton); estradiol and norgestimate (Ortho-Prefest).
HRT, estrogen/testosterone combinations: Esterified estrogens and methyltestosterone (Estratest, Estratest HS).
Similar properties but evidence indicating no or reduced interaction effects:
Progestin-only oral contraceptives, implants, and post-coital contraceptives: Etonogestrel, implant (Implanon),

levonorgestrel, implant (Jadelle, Norplant; Norplant-2); levonorgestrel, oral postcoital contraceptive (Duofem, Escapelle, Levonelle, Levonelle-2, Microlut, Microval, Norgeston, Nor-Levo, Plan B, Postinor-2, Vika, Vikela); medroxyprogesterone, injection (Depo-Provera, Depo-subQ Provera 104); medroxyprogesterone, oral (Cycrin, Provera); NES progestin, implant (ST-1435, Nestorone); norethindrone, oral (norethisterone; Aygestin, Camila, Errin, Jolivette, Micronor, Nor-QD, Ortho-Micronor); norethindrone, injectable (NET EN; Noristerat); norgestrel, oral (Ovrette).

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **3. Possible**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Exogenous estrogen, as oral contraceptive (OC) or estrogen replacement therapy (ERT), enhances magnesium uptake and utilization by soft tissues and bone, thereby moving magnesium from the blood, lowering serum levels, and depleting body stores of magnesium.[136-138]

Research

Decreased levels of serum magnesium have been associated with OCs, in pregnancy, and during ERT in postmenopausal women.[139,140] Seelig[138] has suggested that one mechanism by which estrogen provides cardiovascular support is through its effects on magnesium, particularly the resistance of young women to heart disease and osteoporosis. She also notes that "estrogen-induced shifts of Mg can be deleterious when estrogen levels are high and Mg intake is suboptimal. The resultant lowering of blood Mg can increase the Ca/Mg ratio, thus favoring coagulation. With Ca supplementation in the face of commonly low Mg intake, risk of thrombosis increases." In a controlled clinical study involving 25 healthy women at varying age and duration of menopause and 15 healthy, cycling women of childbearing age, Muneyyirci-Delale et al.[141] found that serum levels of magnesium were inversely related to the serum level of estrogen in both groups.

The use of OCs is associated with unfavorable alterations in magnesium status. In a controlled study, Olatunbosun et al.[142] found that women being administered exogenous estrogen in OC form had significantly lower serum magnesium levels as circulating magnesium shifted from serum to tissues. In a later clinical study of 32 women, mean age 24.2 years, administered an OC containing ethinyl estradiol (0.03 mg) and levonorgestrel (0.15 mg), Blum et al.[137] reported a 26% decrease in serum magnesium after 6 months compared to baseline levels; no clinical signs of magnesium deficiency were observed among these women. Subsequently, Hameed et al.[143] studied serum mineral levels in 50 women taking OCs (Lofeminal) and 50 taking injectable contraceptive (depot medroxyprogesterone acetate and Norigest) and found that there was significant decrease in serum levels of calcium, magnesium, and phosphorus in women taking OCs but significant increase in these minerals in women taking injectable contraceptives.

In a preliminary trial, Herzberg et al.[144] found that osteoporotic postmenopausal women demonstrated reduced urinary excretion of zinc, magnesium, and hydroxyproline after HRT (conjugated estrogens and medroxyprogesterone) for 1 year. Combined use of estrogen and calcium increases the need for magnesium, particularly in the treatment of osteoporosis.[136]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although the clinical research thus far has not focused specifically on the clinical implications of the interaction between estrogen and magnesium, the basic trend suggested by relevant findings points in a clear and relatively consistent direction. Premenstrual syndrome (PMS) and other gynecological conditions are associated with, or more likely to result in, aggravated symptoms or adverse outcomes in the presence of compromised magnesium status, particularly when estrogen dominance or exogenous estrogens are present. The signs of symptomatic hypomagnesemia and those of PMS and related conditions share many features, including appetite loss, nausea and vomiting, sleepiness, weakness, muscle spasms, tremors, and personality changes. Thus, magnesium deficiency is associated with increased risk of PMS,[145,146] and magnesium supplementation can play an important role in preventing and treating PMS,[147,148] particularly in those with hypomagnesemia. Likewise, magnesium and estrogen (at least endogenous estrogen) both have important roles to play toward the therapeutic goals of preventing osteoporosis and supporting cardiovascular health.

The coadministration of magnesium and exogenous estrogen requires an individualized, flexible, and evolving approach to integrative care and clinical management to achieve the desired clinical outcomes effectively. Further research into the characteristic, mechanism, and clinical implications of the interaction between magnesium and estrogen is clearly warranted by its potential importance with both preventive and therapeutic agendas. Pending the outcome of such focused study, supplementation with magnesium, 250 to 350 mg per day, can provide a safe support against estrogen-induced stress on magnesium function and potential drug-induced depletion. Likewise, the coadministration of the two agents might prove advantageous, especially in reducing the risk of adverse effects of exogenous estrogen. Within the practice of integrative medicine, other approaches to supporting hormonal balance and liver conjugation of estrogen are often considered as appropriate to the characteristics and needs of the particular patient, such as exercise, vitamin B_6, natural progesterone, chaste tree *(Vitex agnus-castus)*, and Chinese herbal formulae such as Xiao Chai Hu Tang or Xiao Yao San.

Fentanyl

Fentanyl (Actiq Oral Transmucosal, Duragesic Transdermal, Fentanyl Oralet, Sublimaze Injection).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Not specified; speculatively, magnesium may reset nerve activation thresholds, thus lessening the level of anesthesia necessary to prevent pain.

Research

In a randomized double-blind study involving 46 patients, split into two groups, undergoing arthroscopic knee surgery under total IV anesthesia, Konig et al.[149] found that in a clinical setting with almost identical levels of surgical stimulation, IV magnesium sulfate administration significantly reduced intraoperative and postoperative analgesic requirements using fentanyl for induction and postoperative analgesia, compared with isotonic sodium chloride solution administration.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Fentanyl is an opioid analgesic administered intravenously or through a patch. Further research is warranted to explore the positive findings in this preliminary clinical trial of the synergistic interaction between fentanyl and magnesium sulfate during surgery. Related research into whether oral magnesium administration might interact similarly in patients using fentanyl patches remains to be done. Since all opioids significantly slow intestinal peristalsis, which frequently results in constipation when used for more than a few days, the laxative effects of oral magnesium can also be used as part of a program to normalize bowel function during opioid analgesic therapy.

Fluoroquinolone (4-Quinolone) Antibiotics, Particularly Ciprofloxacin

Evidence: Ciprofloxacin (Ciloxan, Cipro).
Extrapolated, based on similar properties: Cinoxacin (Cinobac, Pulvules), enoxacin (Penetrex), gatifloxacin (Tequin), levofloxacin (Levaquin), lomefloxacin (Maxaquin), moxifloxacin (Avelox), nalidixic acid (Neggram), norfloxacin (Noroxin), ofloxacin (Floxin, Ocuflox), sparfloxacin (Zagam), trovafloxacin (alatrofloxacin; Trovan).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Magnesium salts may decrease the absorption of fluorinated quinolone antibiotics. Numerous studies have demonstrated that antacids containing magnesium, and by extension other magnesium compounds, readily chelate with and reduce absorption of fluoroquinolone antibiotics when administered concurrently.[150-158] Specifically, the antimicrobials appear to be rendered inactive when the 3-carbonyl and 4-oxo functional groups characteristic of medications in this class form chelates with multivalent metal cations, particularly aluminum, magnesium, calcium, iron, and zinc, but also copper, manganese, and possibly sodium.[153,155-166] For example, the absorption of ciprofloxacin is reduced by 50% to 90% in the presence of antacids containing magnesium and aluminum.

Research

Although there is general agreement as to the pattern of interaction between fluoroquinolones and multivalent cations, no published research has specifically involved magnesium supplements. Numerous minerals are known to form chelated complexes with fluoroquinolone antibiotics, or otherwise significantly reduce their absorption and bioavailability (AUC). Research involving magnesium has largely focused on antacids containing magnesium (or conclusions have been extrapolated from research involving aluminum-based antacids).[152,156,157,164,167-174] Given the nature of the apparent mechanism of action and the consensus on the pharmacological principles involved, the probability of similar interactions occurring with magnesium supplements can be reasonably extrapolated from the observed phenomena. Nevertheless, despite similarities, the evidence available on the degree of reduction in fluoroquinolone C_{max} and AUC attributable to aluminum-based antacids cannot reasonably be extrapolated to magnesium supplements.

Clinical Implications and Adaptations

Physicians prescribing fluoroquinolone antibiotics should instruct patients to take magnesium and other mineral supplements (as well as related antacids) as far apart as possible from the medications (at least 6 hours before or 2 hours after antibiotics is usually adequate) to avoid the potential interaction. It is important to note that this interaction concern is only relevant to oral administration of both agents.

Foscarnet

Foscarnet (Trisodium phosphonoformate hexahydrate; Foscavir).

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Magnesium depletion, acute ionized hypocalcemia and hypomagnesemia, hypokalemia, and hypo/hyperphosphatemia are common and often severe adverse effects associated with IV foscarnet. The mechanisms by which foscarnet induces these changes, especially in ionized cations, are not completely understood, although renal impairment is the major toxicity of Foscavir. Foscarnet causes increased elimination of magnesium and other electrolytes in the urine and induces changes in plasma concentrations of total and ionized calcium and magnesium. Foscarnet binds preferentially to the magnesium ion.[175] Foscarnet-induced ionized hypomagnesemia might contribute to ionized hypocalcemia by impairing excretion of preformed PTH or by producing target organ resistance.[176]

Research

In a clinical trial involving 13 male HIV-positive patients who had no active cytomegalovirus (CMV)–associated disease, Noormohamed et al.[175] observed significant foscarnet-induced changes in plasma concentrations of total and ionized calcium and magnesium. The maximal decreases in ionized calcium and magnesium were much more rapid and larger than changes in the plasma concentrations of total calcium and magnesium, and the relative changes in the plasma concentration of ionized magnesium were greater than those of ionized calcium.

In a small study of solid-organ transplant recipients with ganciclovir-resistant CMV infection, Mylonakis et al.[177] reported that magnesium depletion occurred in all six patients within 72 to 96 hours after initiating treatment with a combination of ganciclovir and daily IV foscarnet.

Huycke et al.[176] conducted a randomized, double-blind, placebo-controlled crossover trial involving 12 patients with AIDS and CMV disease to investigate the effect of IV magnesium sulfate on foscarnet-induced ionized hypocalcemia and hypomagnesemia. Parenteral $MgSO_4$, administered in increasing doses, reduced or eliminated foscarnet-induced, acute ionized hypomagnesemia. However, it had no discernible effect on foscarnet-induced, ionized hypocalcemia or associated symptoms, despite significant increases in serum PTH levels.

Reports

In 1993, Gearhart and Sorg[178] reported the first known case of severe hypomagnesemia and other electrolyte disorders (hypocalcemia, hypokalemia, hypophosphatemia) in a patient with AIDS being treated for an exacerbation of CMV retinitis with foscarnet. The symptoms of muscle twitches, tremulousness, and anxiety resolved, and laboratory indices returned to normal after administration of magnesium and other electrolytes and discontinuation of foscarnet.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although the general consensus is that foscarnet causes magnesium depletion, the issue of an effective therapeutic response to foscarnet-induced hypomagnesemia and hypocalcemia remains unresolved. Physicians prescribing and administering foscarnet are advised to monitor magnesium and other electrolytes frequently during foscarnet therapy. Huycke et al.[176] concluded that routine IV administration for patients with normal serum magnesium levels is not recommended during treatment with foscarnet. However, divergent opinions remain as to the accuracy of various methods of assessing magnesium. The duration of treatment with foscarnet will generally affect both the clinical implications of the magnesium depletion pattern and the appropriate diagnostic approach. Furthermore, Gearhart and Sorg[178] noted that concomitant therapy with antianxiety medications may mask the symptoms of electrolyte disorders and should be undertaken with caution. Further research into the clinical significance of these issues and integrative therapeutic options is clearly warranted.

Insulin

Animal-source insulin (Iletin); human analog insulin (Humanlog); human insulin (Humulin, Novolin, NovoRapid, Oralin).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Glucosuria-related hypomagnesuria, nutritional factors and hyperinsulinemia-related hypermagnesuria all contribute to the well-established tendency for magnesium deficiency in patients with diabetes mellitus. Magnesium improves insulin sensitivity as well as insulin secretion in patients with type 2 diabetes.[179]

Research

Diabetes is associated with low magnesium status,[180] and general consensus has existed since the early 1990s on the recognition of "strong associations ... between magnesium deficiency and insulin resistance."[181]

Most researchers have found that magnesium improves insulin sensitivity as well as insulin secretion in patients with type 2 diabetes.[182] In a small clinical trial involving eight older, non–insulin-dependent diabetes mellitus (NIDDM) subjects, Paolisso et al.[183] demonstrated that long-term magnesium administration (2 g/day) can elevate plasma magnesium levels and improve insulin response and action. In a subsequent double-blind trial, dosage appeared crucial, with 1000 mg/day magnesium producing a favorable effect that was not obtained with half that dosage.[184] Eibl et al.[185] showed that a 3-month course of replacement therapy with oral magnesium corrected hypomagnesemia in patients with type 2 diabetes. Johnsen et al.[186] similarly reported that well-regulated NIDDM patients with marked magnesium deficiency responded favorably to oral magnesium. Two studies of the effect of magnesium administration on glucose tolerance in nondiabetic elderly subjects produced mixed results.[187,188]

Nadler et al.[11] found that healthy subjects receiving a low-magnesium diet, adequate to demonstrate reductions in both serum magnesium and intracellular free magnesium in RBCs, produced a significant decrease in insulin sensitivity as well as increased thromboxane synthesis. In a clinical trial involving 16 subjects with insulin-dependent type 1 diabetes mellitus and 30 healthy controls, Sjogren et al.[189] found that oral administration of magnesium hydroxide (500 mg/day) reduced insulin requirements, without changing levels of glycosylated hemoglobin (HbA_{1c}) and glucose, and corrected muscular magnesium and potassium deficiency in the diabetic patients. However, a decade later, in a clinical trial with 50 moderately controlled, insulin-requiring type 2 diabetic patients, randomized to 15 mmol oral magnesium or placebo daily for 3 months, De Valk et al.[190] reported that plasma $[Mg^{++}]$ was higher after magnesium than after placebo, but that significant differences were lacking with regard to erythrocyte $[Mg^{++}]$, glycemic control, lipids, or blood pressure.

Diabetic patients with severe retinopathy have a lower plasma magnesium level than those without retinopathy,[191] and a prospective study demonstrated that plasma magnesium concentration are inversely related to occurrence or progression of retinopathy.[192]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Insulin and magnesium represent important elements of a comprehensive repertoire of therapeutic options appropriate for consideration within a personalized and evolving program of care for individuals with diabetes and cardiovascular sequelae, along with dietary changes, exercise, alpha-lipoic acid, chromium, and omega-3 fatty acids such as fish oil. Initial assessment of renal function and magnesium status as well as regular monitoring and adjustment of insulin levels are important before beginning administration of oral magnesium, which is typically prescribed in the range of 200 to 600 mg of elemental magnesium per day.

Lithium Carbonate

Lithium carbonate (Camcolit, Carbolith, Duralith, Eskalith, Li-Liquid, Liskonum, Litarex, Lithane, Lithobid, Lithonate, Lithotabs, PMS-Lithium, Priadel).

Interaction Type and Significance

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Magnesium and lithium are chemically related and appear to interact and sometimes compete within various physiological functions.[193-195] The consumption of lithium carbonate may cause high blood levels of magnesium.[196-198]

Research

Ramasamy and de Freitas[194] have observed competition between Li^+ and Mg^{++} for ATP in human erythrocytes in vitro using a 31P NMR and optical spectroscopy study. Herzberg and Herzeberg[198] reported a significant gender difference in mean plasma magnesium levels in 44 depressed patients. The authors concluded that such findings suggested an unknown interaction between lithium and magnesium and that magnesium metabolism could play an important role in bipolar disorder and the mode of action of lithium. In a small clinical trial, researchers found that antacids containing magnesium hydroxide did not significantly alter bioavailability of lithium carbonate in six healthy subjects.[199]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although based on reasonable pharmacological principles and representing a plausible likelihood of occurrence, the clinical significance of the proposed interaction between lithium and magnesium remains largely unstudied. Nevertheless, physicians prescribing lithium carbonate are advised to ask such patients if they are taking magnesium. Initial assessment of magnesium status (and renal function) and regular monitoring of both lithium levels and magnesium levels are important to avoid excessive magnesium levels, if it is determined that both agents are therapeutically appropriate and strategically necessary.

Macrolide Antibiotics

Azithromycin (Zithromax), clarithromycin (Biaxin), dirithromycin (Dynabac), erythromycin, oral (EES, EryPed, Ery-Tab, PCE Dispertab, Pediazole); troleandomycin (Tao).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Some macrolide antibiotics, including erythromycin, may interfere with the absorption and activity of magnesium and other nutrients, particularly with extended treatment.

Research

The evidence pertaining to the effects of most macrolide antibiotics on magnesium is strongly suggestive but remains preliminary or inconclusive.[200]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing extended courses of erythromycin or other macrolide antibiotics may find it prudent to recommend magnesium supplementation (e.g., 300 mg/day orally) given the potential for interference with magnesium absorption and functions. Monitoring of magnesium levels and compensatory supplementation may be especially appropriate for patients with cardiovascular conditions or pathophysiological dysfunction in whom magnesium depletion might be clinically significant.

Misoprostol

Misoprostol (Cytotec); combination drug: misoprostol and diclofenac (Arthrotec).

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**, but treated as ● **Consensus**

Effect and Mechanism of Action

The most common adverse effect associated with misoprostol, a prostaglandin E_1 analog, is mild, transient diarrhea, often accompanied by abdominal cramps. Excessive magnesium intake can also cause diarrhea. Concomitant use of the two agents might result in an additive effect and subsequent occurrence or aggravation of diarrhea or other adverse effects.[201]

Research

No specific evidence; possibility of occurrence is considered pharmacologically self-evident.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing misoprostol are advised to inform patients of the risk of diarrhea associated with the medication and the potential aggravation of adverse effects by concomitant magnesium intake. Drug-induced diarrhea can usually be minimized by administration of misoprostol after meals and at bedtime. Magnesium administration might be temporarily held in abeyance in some cases where the nutrient is considered strategically important but secondary in importance to the misoprostol in terms of tactical therapeutics.

Neuromuscular Blocking Agents

Evidence: Rocuronium, suxamethonium (succinylcholine), tubocurarine, vecuronium.

Extrapolated, based on similar properties: Atracurium, cisatracurium, doxacurium, metocurine iodide, mivacurium, pancuronium, pipecuronium.

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Magnesium salts, particularly magnesium sulfate given parenterally, can increase and prolong (up to eightfold) the effects of neuromuscular blocking agents.[202-207] Many substances alter the pharmacokinetics of neuromuscular blockers, especially

those that depend on renal excretion, such as magnesium. Furthermore, some degree of additive effect is also operative because magnesium itself exerts significant neuromuscular blocking activity. These effects are at least partly caused by magnesium's marked inhibitory effect on acetylcholine release.[208]

Research

In a study involving women with toxemia of pregnancy undergoing cesarean birth, Morris and Giesecke[202] reported that patients receiving IV magnesium required approximately 65% of the dosage of succinylcholine (compared with those not receiving magnesium) to achieve adequate neuromuscular blocking activity.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Concomitant use of IV magnesium may enable neuromuscular blocking activity to be achieved with lower doses of neuromuscular blockers. Beyond such intentional coadministration, this interaction pattern is primarily of clinical significance in patients with increased serum magnesium concentrations; in such patients, unintentional additive effects could be of major severity. Physicians administering neuromuscular blocking agents are advised to assess initial magnesium status and closely monitor parameters of both substances if present together.

Penicillamine

Penicillamine (D-Penicillamine; Cuprimine, Depen).

Interaction Type and Significance

◈◈ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Penicillamine and magnesium salts tend to form complexes, resulting in reduced magnesium absorption and inhibited activity of both substances. However, magnesium administration may reduce adverse effects of penicillamine in individuals who are magnesium deficient or who have become magnesium depleted due to action of the drug.

Research

The primary action of penicillamine is chelation of minerals and inhibition of their absorption and bioavailability. Formation of such complexes with magnesium inherently reduces availability of penicillamine for its intended therapeutic action. In a randomized crossover trial involving six healthy men given a single 500-mg oral dose of penicillamine, Osman et al.[209] observed that coadministration of a magnesium-containing antacid reduced the peak plasma level of penicillamine to 66% of those with the fasting dose. However, the antacid used contained both magnesium hydroxide and aluminum hydroxide, and the researchers did not attempt to distinguish the respective effects of the two components.

Use of high doses of penicillamine over an extended time can result in significant inactivation of magnesium and subsequent depletion. Seelig[210] hypothesized that autoimmune complications of D-penicillamine could result from magnesium and zinc depletion and pyridoxine inactivation. In a clinical trial involving more than 50 patients on long-term high-dose penicillamine therapy for advanced stages of autoimmune diseases, she found that coadministration of magnesium, along with zinc, pyridoxine, and vitamins B_1, B_{12}, and E, resulted in fewer adverse reactions than usual for patients treated with penicillamine alone.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing penicillamine are advised to assess magnesium (and zinc) status at the initiation of treatment, especially when anticipating long-term high-dose penicillamine therapy. When magnesium has been determined to represent an essential element of the therapeutic strategy for the given patient, penicillamine should be administered at least 2 hours away from magnesium preparations (or magnesium-containing antacids).

Pentamidine

Pentamidine (NebuPent, Pentacarinat, Pentam 300, Pneumopent).

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **3. Possible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Pentamidine, an antiprotozoal medication, is known to decrease magnesium levels.[8]

Research

In vitro research suggests that pentamidine binds to a magnesium-binding site of the ribozyme in the target microbe. Zhang et al.[211] demonstrated that pentamidine inhibits catalytic activity of group I intron Ca.LSU from the transcripts of the 26S rRNA gene of *Candida albicans* by altering RNA folding.

Reports

Cortes et al.[212] reported two cases of hypocalcemia and hypomagnesemia associated with pentamidine therapy in patients with human immunodeficiency virus (HIV) infection. Otsuka et al.[213] reported a case in which torsades de pointes developed subsequent to pentamidine therapy for *Pneumocystis carinii* pneumonia in a patient with acute myelogenous leukemia. Torsades de pointes resolved with administration of magnesium sulfate and discontinuation of the IV pentamidine; however, sinus bradycardia and prolonged QT interval persisted. The authors recommended "careful monitoring of the electrocardiogram" during IV pentamidine therapy.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing pentamidine are advised initially to assess and then regularly monitor magnesium (and potassium) status and administer compensatory nutrients as appropriate. Complementary therapies to support healthy cardiovascular and immune systems are usually appropriate in an integrative approach to treatment of immunocompromised individuals.

Quinidine and Related Antiarrhythmic Drugs

Evidence: Quinidine (Quinaglute, Quinidex, Quinora).
Extrapolated, based on similar properties: Amiodarone (Cordarone, Pacerone), disopyramide (Norpace), dofetilide (Tikosyn), flecainide (Tambocor), ibutilide (Corvert), procainamide (Procan-SR, Pronestyl), sotalol (Betapace, Betapace AF, Sorine).
See also Sotalol and Related Beta-1-Adrenoceptor Antagonists (Beta-1-Adrenergic Blocking Agents).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**
≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **2. Probable**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Quinidine, and other antiarrhythmic drugs, may worsen cardiac rhythm disorders and increase the risk of death, especially in individuals with a history of a heart attack. In particular, quinidine causes torsades de pointes under certain conditions, particularly hypokalemia, hypomagnesemia, and other electrolyte abnormalities. Potent suppression of a potassium channel subunit current by quinidine is a likely contributor to torsades de pointes arrhythmias.[214] Magnesium may prevent or reverse such quinidine-induced aggravation of cardiac arrhythmias. However, research into antacid-drug interactions shows that intragastric release of free aluminum and magnesium ions can induce potent effects on drug pharmacokinetics and GI function, particularly with drug-induced changes in GI motility or alterations in gastric and urinary pH. Direct adsorption by magnesium, or other mineral salts, may also result in decreased drug bioavailability, although not necessarily to a clinically significant degree.[215]

Research

Hypomagnesemia, especially in the presence of hypokalemia or other electrolyte abnormalities, is associated a range of adverse effects, including quinidine-related torsades de pointes, and interference with the antiarrhythmic activity of quinidine. Mutations in a gene encoding a potassium channel subunit (HERG) can be related to the long-QT (LQT) syndrome characteristic of torsades de pointes, a polymorphic ventricular arrhythmia. Pharmacological suppression of repolarizing potassium currents is also a mechanism causing the acquired LQT syndrome. Intravenous magnesium sulfate is often effective in reversing torsades de pointes induced by quinidine or other drugs, but the molecular basis of the mechanism involved in this action is not fully understood. In an in vitro study, Po et al.[214] found that increasing extracellular Mg^{++} did not relieve the inhibition of HERG currents by quinidine, but did cause additional suppression. These authors concluded that modulation of this important K^+ current is not the mechanism by which IV magnesium terminates drug-induced LQT and torsades de pointes. Further research into electrolyte function in cardiac tissue, related drug interactions and depletion, and individual genomic and pharmacogenomic variability is warranted and can benefit from an integrative approach to multidisciplinary therapeutic interventions.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Within a comprehensive therapeutic repertoire, quinidine and magnesium represent important options appropriate for consideration in crafting a program of care for individuals with arrhythmias and other cardiovascular conditions. Treatment of arrhythmias, hypertension, or other cardiovascular conditions using medications that do not deplete vital nutrients or otherwise introduce electrolyte abnormalities is preferable, especially patients at risk of arrhythmias or receiving drugs such as quinidine. Regular monitoring and appropriate nutrient administration are important therapeutic tools when recourse to more deleterious agents is deemed necessary. Low potassium and magnesium concentrations not only contribute to or cause cardiac arrhythmias, but also interfere with the efficacy or enhance the toxicity of many drugs typically used to treat patients with heart disease. Physicians prescribing quinidine, especially in conjunction with potassium-depleting diuretics, are advised initially to assess and then periodically monitor potassium and magnesium status and consider recommending coadministration of both minerals. Clinical care within an integrative setting might also emphasize a diet rich in vitamins, minerals, and antioxidants and incorporate hawthorn *(Crataegus oxyacantha)*, L-carnitine, coenzyme Q10, and other nutrients as part of an individualized and evolving approach to cardiovascular therapeutics.

Sodium Polystyrene Sulfonate

Sodium Polystyrene Sulfonate (SPSS)

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**
◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **4. Plausible**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Sodium polystyrene sulfonate (SPSS), often administered for the acute and chronic treatment of hyperkalemia, may alter magnesium levels and interfere with the therapeutic effects of magnesium. SPSS appears to increase sodium levels because of exchange for calcium and magnesium, thereby increasing susceptibility to magnesium depletion.[216]

Research

In vitro research investigating methods for reducing potassium intake indicates that, when used in hyperkalemia as a pretreatment for making a low-potassium formula, SPSS appears to lower calcium and magnesium levels while elevating sodium levels.[216]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Concomitant administration of SPSS may reduce the efficacy of therapeutic or supplemental magnesium intake and could potentially induce a nutrient depletion pattern impacting magnesium. Such repercussions may simply need to be taken into account when adopting SPSS as an appropriate therapeutic tactical element and introduce no significant clinical complications. However, compensatory magnesium intake may be necessary if magnesium constitutes an essential component of the therapeutic strategy and long-term SPSS is contemplated.

Sotalol and Related Beta-1-Adrenoceptor Antagonists (Beta-1-Adrenergic Blocking Agents)

Oral forms (Systemic)

Evidence: Sotalol (Betapace, Betapace AF, Sorine)

Extrapolated, based on similar properties: Acebutolol (Sectral), atenolol (Tenormin); combination drugs: atenolol and chlortalidone (Co-Tendione, Tenoretic), atenolol and nifedipine (Beta-Adalat, Tenif); betaxolol (Kerlone), bisoprolol (Zebeta), carteolol (Cartrol), esmolol (Brevibloc), labetalol (Normodyne, Trandate), metoprolol (Lopressor, Toprol XL); combination drug: metoprolol and hydrochlorothiazide (Lopressor HCT); nadolol (Corgard), nebivolol (Nebilet), oxprenolol (Trasicor), penbutolol (Levatol), pindolol (Visken), propranolol (Betachron, Inderal LA, Innopran XL, Inderal); combination drug: propranolol and bendrofluazide (Inderex); timolol (Blocadren).

See also Quinidine and Related Antiarrhythmic Drugs.

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management.**

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

Probability: **3. Possible**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Magnesium compounds may reduce absorption and bioavailability of some beta blockers. Unintentional coadministration of some beta blockers, such as sotalol, and a magnesium-containing antacid appear to reduce serum levels of the drug.[217] However, beta blockers can induce numerous metabolic disturbances, including dose-related decreases in plasma potassium, phosphate, and corticosteroids and significant hypocalcemia and hypomagnesemia, that may result in excessive cardiac depressant effects, such as bradycardia, asystole, and sinus arrest. In particular, sotalol can produce an arrhythmia known as torsades de pointes. Intravenous magnesium sulfate can be effective in reversing torsades de pointes and has been observed to abolish inadequate kinetics of frequency adaptation of the Q-aT interval,[218] but the molecular basis of this effect is not understood.[214] Further, magnesium can theoretically exert many effects similar to those of a calcium channel blocker, so standard cautions regarding the potential for an additive interaction with beta blockers may be relevant to magnesium administration.

Research

Magnesium appears to be an effective adjuvant to beta-blocker therapy, especially in cases involving arrhythmia or atrial fibrillation. As with other antiarrhythmic drugs, beta blockers can also induce ventricular arrhythmias. Stark et al.[218] investigated the effects of sotalol alone and in combination with $MgSO_4$ and the Q-aT interval during abrupt changes in heart rate. In an animal experiment, they found that sotalol led to inadequate kinetics of rate adaptation of the Q-aT interval (indicated by high amplitude of Q-aT interval change, especially within first beat after abrupt change in pacing rate) and that magnesium sulfate abolished this adverse effect. Frick et al.[219] investigated the effect of administering sotalol and magnesium on the incidence of atrial fibrillation after elective direct-current cardioversion of persistent atrial fibrillation. They found that occurrence of atrial fibrillation was significantly reduced by the administration of sotalol or magnesium individually, but that combination therapy was even more effective. Subsequently, in a randomized clinical trial with 207 consecutive coronary artery bypass patients, Forlani et al.[220] determined that the concomitant administration of sotalol and magnesium can prevent atrial fibrillation, a common complication after coronary artery bypass grafting.

Reports

In at least two published reports, IV magnesium effectively treated torsades de pointes in individuals taking sotalol.[221,222]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Research on coadministration of magnesium with sotalol appears promising, but available evidence is inadequate to warrant a general recommendation that individuals prescribed sotalol also take an oral magnesium supplement to prevent known adverse effects. When the patient's history and cardiac risk factors indicate that magnesium coadministration might be clinically appropriate, initial and regular monitoring of magnesium (and potassium) levels is necessary. Nevertheless, prudence suggests that any magnesium preparation should be taken at least 2 hours away from sotalol or related medications, even though the cautionary research is based on magnesium-containing antacids. Such metabolic monitoring is inherently part of critical care situations where IV magnesium (sulfate) may be indicated.

Sulfonylurea Hypoglycemics

Acetohexamide (Dymelor), chlorpropamide (Diabinese), glimepiride (Amaryl), glyburide (glibenclamide; Diabeta, Glynase Prestab, Glynase, Micronase, Pres Tab), glipizide (Glucotrol; Glucotrol XL), tolazamide (Tolinase), tolbutamide (Orinase; Tol-Tab); combination drugs: glipizide and metformin (Metaglip), glyburide and metformin (Glucovance).

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability: **3. Possible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Magnesium intake may improve insulin sensitivity and secretion.[179] Concomitant ingestion of magnesium hydroxide, observed primarily in the form of antacids, with glipizide and glyburide can significantly enhance the rate and extent of absorption and efficacy of both medications and thereby facilitate early insulin and glucose responses.[223-226] These pharmacokinetic and pharmacodynamic interactions, as well as the cumulative effect of two therapies that can effectively alter blood glucose response, result in a potentially significant combination that might excessively lower blood glucose levels or enable more effective therapy or modification of dosage regimen.

Research

Diabetes is associated with low magnesium status,[180] and general consensus has existed since the early 1990s on the recognition of "strong associations . . . between magnesium deficiency and insulin resistance."[181]

Most researchers have found that oral magnesium improves insulin sensitivity as well as insulin secretion in patients with type 2 diabetes.[182] In a small clinical trial involving eight older, non-insulin-dependent diabetes mellitus (NIDDM) subjects, Paolisso et al.[183] demonstrated that long-term magnesium administration (2 g/day) can elevate plasma magnesium levels and improve insulin response and action. In a subsequent double-blind trial, dosage appeared crucial, with 1000 mg/day of magnesium producing a favorable effect that was not obtained with half that dosage.[184] Eibl et al.[185] showed that a 3-month course of replacement therapy with magnesium corrected hypomagnesemia in patients with type 2 diabetes. Johnsen et al.[186] similarly reported that well-regulated NIDDM patients with marked magnesium deficiency responded favorably to oral magnesium. Two studies of the effect of magnesium supplementation on glucose tolerance in nondiabetic elderly subjects produced mixed results.[187,188]

Looking at a group of poorly controlled type 2 diabetic patients with hypomagnesemia, hypermagnesuria, and hypercalciuria, McBain et al.[227] observed that treatment with glipizide was associated with a significant rise in serum magnesium levels. Numerous pharmacological studies have demonstrated that the rate and extent of absorption of glipizide and glyburide, as well as their efficacy, are significantly enhanced by the concomitant administration of magnesium hydroxide.[223-226] For example, in a randomized trial with eight healthy people, Kivisto and Neuvonen[224] found that 850 mg magnesium hydroxide accelerated absorption of glipizide and increased early insulin and glucose responses.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The clinical implications of potential interaction(s) between magnesium and sulfonylurea drugs, particularly glipizide, glimepiride, and glyburide, largely depend on physician-patient communication and clinical management based on a coherent strategy. Magnesium can play an important role within a comprehensive, individualized, and evolving approach to clinical management of insulin resistance, dysglycemia, diabetes, and cardiovascular sequelae in conjunction with very-low-fat (and/or high-protein) diet, aerobic exercise, and appropriate weight reduction, as well as a coordinated nutraceutical program including chromium, multiple networked antioxidants (including mixed tocopherols and alpha-lipoic acid), soluble fiber, and possibly taurine.[228] Within a clinical context of collaboration by health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics, using magnesium in conjunction with sulfonylurea drugs at least can address the probability of magnesium deficiency in the susceptible individuals and may enhance the blood glucose–lowering effects of the medication. However, such concomitant use outside of integrative therapeutics and regular monitoring may increase the risk of hypoglycemia from an excessive additive interaction.

Tetracycline Antibiotics

Demeclocycline (Declomycin), doxycycline (Atridox, Doryx, Doxy, Monodox, Periostat, Vibramycin, Vibra-Tabs), minocycline (Dynacin, Minocin, Vectrin), oxytetracycline (Terramycin), tetracycline (Achromycin, Actisite, Apo-Tetra, Economycin, Novo-Tetra, Nu-Tetra, Sumycin, Tetrachel, Tetracyn); combination drugs: chlortetracycline, demeclocycline, and tetracycline (Deteclo); bismuth, metronidazole, and tetracycline (Helidac).

Interaction Type and Significance

◈◈ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

Probability:
2. Probable

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Magnesium salts can chelate with tetracycline medications and thereby interfere with their absorption and possibly reduce their bioavailability and effectiveness; although one study suggests that the complexed tetracycline may be more bioavailable.[229-236] This interaction occurs not only with supplemental magnesium but also with many antacids (e.g., Pepto-Bismol) that contain aluminum-magnesium hydroxide. Conversely, the formation of such complexes inherently reduces magnesium absorption and bioavailability and could contribute to magnesium depletion over an extended period. Furthermore, in vitro studies indicate that chelates of magnesium and tetracycline may play a role in the toxicity of tetracycline.

Research

The findings of Neuvonen[229] (1976) are typical of most subsequent research in concluding that tetracyclines form chelates with divalent and trivalent cations, including iron, aluminum, magnesium, and calcium. The team of Lambs, Brion, and Berthon has written extensively in the area of metal ion–tetracycline interactions. One paper states that simultaneous ingestion of minocycline and magnesium (as well as calcium, iron, or zinc) can decrease the absorption of both the medication and the mineral.[232] In another paper, however, they reported that although magnesium-tetracycline complexes are likely to form, the resulting complex may actually be more bioavailable than uncomplexed tetracycline because of a higher degree of membrane diffusion.[231]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

In general, physicians prescribing tetracycline-class antibiotics should advise their patients to avoid using magnesium-based antacids and supplemental magnesium unless a patient's clinical care demands otherwise. Neuvonen[229] noted that the "pharmacokinetic interactions in absorption of tetracyclines [are] likely to be clinically significant in cases where the infecting pathogens are moderately resistant to tetracyclines and relatively high serum concentrations are needed for proper bacteriostasis." Nevertheless, tetracycline and antacids are often used together in combination therapies for *Helicobacter pylori* infection.

It is generally recommended that tetracycline be taken on an empty stomach, with a full glass of water, 1 hour before or 2 hours after ingestion of any supplements, food, or other drugs. However, an interval of 3 hours between the ingestion of tetracyclines and minerals such as magnesium is usually more effective in preventing this potential interaction.

Theophylline/Aminophylline

Theophylline/aminophylline (Phyllocontin, Slo-Bid, Slo-Phyllin, Theo-24, Theo-Bid, Theocron, Theo-Dur, Theolair, Truphylline, Uni-Dur, Uniphyl); combination drug: ephedrine, guaifenesin, and theophylline (Primatene Dual Action). See also Epinephrine in Theoretical, Speculative, and Preliminary Interactions Research.

Interaction Type and Significance

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Theophylline therapy is associated with magnesium depletion in the chronic asthmatic patient population characterized by magnesium deficiency. Magnesium can be an effective bronchodilator and, in various forms, is used in the treatment of chronic and acute asthma.

Research

Preliminary evidence indicating that theophylline can promote hypomagnesemia and hypokalemia concurs with clinical observations of a tendency for individuals taking this medication to develop potassium and magnesium deficiency.[237,238] In a study involving 869 patients treated with theophylline, Flack et al.[239] found that patients with measurable theophylline (concentrations >5.5 μmol/L) had a higher risk of hypokalemia, hyponatremia, hyperglycemia, hypophosphatemia, and hypomagnesemia than individuals in a control group of 350 inpatient and outpatient adults and children with no history of reactive airways disease or theophylline exposure.[239] Likewise, in a study of 93 chronic stable asthmatic patients on regular follow-up in an asthma clinic, Alamoudi[17] found that magnesium deficiency is associated with the occurrence and severity of asthma, particularly airway hyperreactivity, wheeze, and impairment of lung function. This paper concluded that hypomagnesemia is common in chronic asthmatic patients, and those with low serum magnesium tend to be hospitalized more than those with normal magnesium. Hypomagnesemia is also associated with more severe asthma.

Reports

Numerous case reports have documented hypomagnesemia and its respiratory, neurological, and cardiac sequelae subsequent to chronic theophylline therapy or theophylline overdose.[240-243] Chevalier et al.[244] reported the case of a patient with ischemic heart disease complicated by left ventricular failure and chronic asthma who had ventricular tachycardia induced by theophylline overdose and responded to IV magnesium chloride.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Magnesium as a nutritional therapy in chronic care and as an infusion in emergency care can play an important role in an integrative approach to the prevention and treatment of asthma, particularly to prevent or reverse hypomagnesemia resulting from, and or act therapeutically in concert with, theophylline therapy. Administration of oral magnesium (300-600 mg/day) is often appropriate for individuals with asthma (or other magnesium-responsive conditions), in whom theophylline use over an extended period might induce magnesium depletion and interfere with magnesium's therapeutic or preventive action. Physicians prescribing theophylline are advised initially to assess and then regularly monitor magnesium status and correspondingly test renal function in individuals at risk for compromised ability to tolerate sustained magnesium administration, if determined to be appropriate. Magnesium sulfate infusions may be efficacious in the emergency care of individuals with acute asthma exacerbations, either in conjunction with beta-2 agonists via nebulizer, IV aminophylline, corticosteroids, or other first-line conventional therapies or in nonresponders.[245]

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Evidence: Warfarin (Coumadin, Marevan, Warfilone). Extrapolated, based on similar properties: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **4. Plausible**

Evidence Base: ▽ **Mixed**

Effect and Mechanism of Action

Magnesium, as well as other minerals such as iron and zinc, may bind with warfarin or dicumarol.[246] However, the evidence is mixed as to whether such chelation reduces or enhances absorption and activity of dicumarol anticoagulants.[226,247] Formation of such complexes might also reduce magnesium absorption and bioavailability and could interfere with the effectiveness of oral magnesium as a preventive or therapeutic agent. Magnesium also exerts some degree of effect on the warfarin-albumin interaction.

Research

Testing four antacid preparations using an in vitro experimental model, McElnay et al.[248] found that magnesium trisilicate, a poorly absorbable form of magnesium never used as a nutrient source, although sometimes used in laxative preparations, decreased intestinal absorption of warfarin sodium by 19%. However, Neuvonen and Kivisto[226] reviewed the relevant literature and noted that magnesium hydroxide, as an antacid, increased absorption of dicumarol most likely because of chelate formation. In contrast, antacids containing both aluminium hydroxide and magnesium hydroxide appeared to produce no net change in the absorption of dicumarol, with aluminium hydroxide counterbalancing the enhancing effect of magnesium hydroxide.[249] Following the work of van der Giesen and Wilting[250] on the magnesium effect on the warfarin-albumin interaction, Perez Gallardo[251] conducted an in vitro experiment investigating the binding of warfarin to human serum albumin in the presence of several concentrations of calcium and magnesium, as chloride compounds.

He found that the free fraction of warfarin remained constant until calcium or magnesium reached concentrations of 50 mmol/L, at which point the binding fell to 92%. He concluded that displacement of bound warfarin can be expected only if the plasma concentrations of calcium or magnesium and chloride are significantly elevated.

Clinical Implications and Adaptations

Although the chemistry of common mineral nutrients binding warfarin is well founded, the frequency of occurrence is uncertain, its nature remains unclear and effects potentially variable, and conclusive evidence of the clinical significance of this interaction is lacking. Nevertheless, physicians prescribing warfarin are advised to recommend to patients that they separate warfarin administration from intake of magnesium (or iron or zinc) supplements (or magnesium-containing antacids) by at least 2 hours. Physician-patient communication is especially important in the event that individuals undergoing anticoagulant therapy are taking magnesium or any other mineral supplements. Regular monitoring of international normalized ratio (INR) is critical so that warfarin levels can be adjusted accordingly.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Captopril

Captopril (Capoten); combination drug: captopril and hydrochlorothiazide (Acezide, Capto-Co, Captozide, Co-Zidocapt).

Both captopril (an ACE inhibitor) and magnesium can be used in the treatment of hypertension. Captopril increases lymphocyte magnesium levels, although possibly only in patients with preexisting low levels.[252,253] This report of an observed interaction may be considered as preliminary or clinically insignificant. However, the therapeutic role of magnesium can be especially important in the population who would most likely be prescribed captopril. In particular, individuals with CHF, such as those noted in the research, tend both to be deficient in magnesium and to benefit therapeutically from magnesium. Thus, the issue of initial and regular monitoring of magnesium levels, along with cardiac function and other prognostic parameters, is essential to effective management of integrative therapeutics.

Cholestyramine

Cholestyramine (Locholest, Prevalite, Questran).

In animal research, cholestyramine produced an increased urinary excretion of magnesium, as well as other metabolic alterations.[254] A pattern of magnesium depletion resulting from this potential interaction could be counterproductive to the overall therapeutic strategy and detrimental to achieving the desired clinical outcomes (i.e., reducing mortality from cardiovascular disease). Supplementation with oral magnesium, typically 300 to 400 mg per day, preferably as part of a balanced multimineral formulation, could prevent nutrient depletion and deficiency. Evaluation of initial magnesium status and regular monitoring may be appropriate in some patients, especially anyone at risk of compromised renal function. Supplementation with fat-soluble vitamins is generally also indicated in patients taking cholestyramine.

Cycloserine

Cycloserine (Seromycin).

Cycloserine may interfere with absorption of magnesium (and calcium).[255] On the other hand, pharmacokinetics of cycloserine are minimally affected by magnesium-containing antacids[256] and thus at least as unlikely to be affected by supplemental magnesium. The probability of occurrence and clinical significance of these potential interactions remain uncertain pending substantive evidence from controlled clinical trials. Concomitant magnesium may be appropriate to address the potential for magnesium depletion with cycloserine use over an extended period and might be particularly relevant in patients with cardiovascular disease, asthma, or other conditions that tend to be magnesium-sensitive.

Docusate

Docusate (Colace, Surfak).

A single case report suggests that chronic use of docusate as a stool softener during and after pregnancy resulted in hypomagnesemia in a woman and her newborn infant.[257] The clinical significance and probability of occurrence of this potential interaction remains uncertain pending substantive evidence from controlled clinical trials. Supplemental magnesium may be appropriate to address the potential for magnesium depletion with docusate use over an extended period, particularly in patient populations at increased risk of magnesium deficiency.

Epinephrine

Epinephrine (Adrenaline, epi; Adrenalin, Ana-Gard, AsthmaHaler, AsthmaNefrin, Bronchaid, Bronkaid Mist, Brontin Mist, Epifin, Epinal, EpiPen, Epitrate, Eppy/N, Medihaler-Epi, Primatene Mist, S-2, Sus-Phrine; epinephrine, injectable: Adrenalin Chloride Solution, EpiPen Auto-Injector).

Hormones associated with stress response, including epinephrine, are known to reduce intracellular concentrations of potassium and magnesium.[258] Thus, endogenous catecholamine release during stress or acute illness can contribute to the hypomagnesemia, such as that seen in acutely ill patients.[259] In particular, catecholamines can intensify cellular magnesium depletion. The detrimental and mutually enhancing effects of catecholamine excess and magnesium deficiency can be particularly deleterious to the myocardium. Animal research has shown that magnesium supplementation can reduce the ultrastructural features of myocardial damage induced by epinephrine without an effect on changes in intracellular distribution of calcium induced by epinephrine.[260] Also, magnesium is indicated for surgery of pheochromocytoma based on its calcium channel–blocking properties and its activity of lowering the release of epinephrine.[261] Even though controlled human trials investigating the effects of epinephrine administration on magnesium status are lacking, physicians prescribing epinephrine for extended periods can consider whether supplementing magnesium is appropriate, especially in individuals susceptible to magnesium depletion and its potential sequelae.

Histamine (H_2) Receptor Antagonists

Cimetidine (Tagamet; Tagamet HB), famotidine (Pepcid RPD, Pepcid, Pepcid AC), nizatidine (Axid, Axid AR), ranitidine (Zantac); ranitidine, bismuth, and citrate (Tritec).

Concerns regarding potential interaction between H_2 blockers, particularly ranitidine, and magnesium does not primarily originate with a drug-nutrient interaction per se. Instead, research on the interaction between magnesium hydroxide and ranitidine has found that some antacids reduce the bioavailability of the H_2 receptor antagonists. This is particularly true when ranitidine is used at the same time as high doses of the relevant antacids. Bachmann et al.[262] found that

among healthy subjects (i.e., who would not normally use the drug) a magnesium-aluminum hydroxide antacid decreased ranitidine absorption by 20% to 25% when the two substances were taken at the same time.

In relation to antacid use, the potential for interaction can be reduced by taking the H_2 blocker at least 2 hours before or after any antacid containing aluminum or magnesium. There is concern that a multivitamin/mineral supplement containing magnesium could have the same effect, especially if the magnesium is in the form of magnesium hydroxide. In such cases, caution would advise taking the H_2 blocker at least 2 hours before or after the magnesium-containing supplement.

Hydroxychloroquine and Chloroquine

Hydroxychloroquine (Plaquenil), chloroquine (Aralen, Aralen HCl).

Research involving chloroquine[263] suggests that oral magnesium intake may reduce blood levels of hydroxychloroquine and thereby decrease its effectiveness. Pending clinical trials providing more conclusive evidence and clarification, physicians prescribing hydroxychloroquine for conditions such as arthritis are advised to instruct patients to take magnesium preparations separate from these medications.

Isoniazid and Related Antitubercular Agents

Isoniazid (isonicotinic acid hydrazide, INH; Laniazid, Nydrazid); combination drugs: isoniazid and rifampicin (Rifamate, Rimactane); isoniazid, pyrazinamide, and rifampicin (Rifater).

Isoniazid appears to interfere with the activity of many nutrients, including magnesium. Human trials indicate that coadministration of magnesium-based antacids does not significantly alter isoniazid parameters.[264] Supplementation with a multivitamin/mineral formulation is advised for individuals undergoing long-term isoniazid therapy.

Magnesium-Containing Antacids

Magnesium carbonate combination drug: magnesium carbonate, aluminum hydroxide, alginic acid, and sodium bicarbonate (Gaviscon Extra Strength Tablets, Gaviscon Regular Strength Liquid, Gaviscon Extra Strength Liquid); magnesium hydroxide (Phillips' Milk of Magnesia MOM); combination drugs: magnesium hydroxide and aluminum hydroxide (Advanced Formula Di-Gel Tablets, Co-Magaldrox, Di-Gel, Gelusil, Maalox, Maalox Plus, Mylanta, Wingel); magnesium hydroxide and calcium carbonate (Calcium Rich Rolaids); magnesium hydroxide, aluminum hydroxide, calcium carbonate, and simethicone (Tempo Tablets); magnesium trisilicate and aluminum hydroxide (Adcomag trisil, Foamicon); magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets).

Concomitant use of supplemental magnesium and these antacids for an extended period might theoretically induce a magnesium excess. However, apart from individuals with compromised renal function, this is doubtful in light of general knowledge of magnesium, its minimal toxicity, and the difficulty in accumulating excessive magnesium levels in tissue.

The potential for interactions involving antacids depends on the chemistry and physical properties of the antacid preparation. The intragastric release of free aluminum and magnesium ions has potent effects on GI function and on drug pharmacokinetics. Antacid-drug interactions may occur secondary to changes in GI motility or alterations in gastric and urinary pH. Direct adsorption also results in decreased drug bioavailability.[215]

Mycophenolate

Mycophenolate (CellCept).

Oral magnesium salts, particularly within antacids, can inhibit absorption of mycophenolate, an immunosuppressive agent. However, even though a magnesium-containing antacid can reduce absorption and lower AUC of mycophenolic acid 15% and C_{max} by 37% (compared with fasting), and plasma mycophenolic acid parameters similarly, such "changes are small in comparison with the interpatient variability and are not likely to have clinically major effects."[265]

Metformin and Related Biguanides

Evidence: Metformin (Dianben, Glucophage, Glucophage XR). Extrapolated, based on similar properties: Buformin (Andromaco Gliporal, Buformina); metformin combination drugs: glipizide and metformin (Metaglip); glyburide and metformin (Glucovance); phenformin (Debeone, Fenformin).

Looking at a group of poorly controlled type 2 diabetic patients with hypomagnesemia, hypermagnesuria, and hypercalciuria, McBain et al.[227] observed that patients treated with metformin therapy demonstrated reduced urinary magnesium excretion but remained hypomagnesemic and hypercalciuric. Given the known associations between magnesium levels and insulin sensitivity, controlled clinical research is warranted. Pending such trials, the clinical significance of this potential interaction remains unclear.

Nitrofurantoin

Nitrofurantoin (Furadantin, Macrobid, Macrodantin).

Mannisto[266] reported that coadministration of nitrofurantoin (100 mg) and a magnesium-aluminum antacid reduced the bioavailability of the nitrofurantoin by approximately 25%. In a study with six healthy male subjects, Naggar and Khalil[267] observed that magnesium trisilicate, a poorly absorbable form of magnesium never used as a nutrient, but sometimes used in combination with other mineral salts as a laxative, reduced the rate and extent of intestinal absorption and thus the bioavailability of nitrofurantoin. An in vitro experiment showed that magnesium oxide, a form of magnesium often used in supplements, exhibited intermediate adsorptive powers. After administering oral nitrofurantoin (200 mg) to 11 subjects in five different suspension materials, Soci and Parrott[268] found that the viscosity effect of colloidal magnesium aluminum silicate slowed absorption and urinary excretion of the medication, thus delaying the time of the maximum excretion rate without a decrease in bioavailability. The clinical significance of these findings remains unclear, particularly their relationship, if any, to magnesium supplements. Nevertheless, physicians prescribing nitrofurantoin may find it prudent to recommend to patients that magnesium in any form be taken at least 2 hours away from the medication.

Potassium-Sparing Diuretics

Amiloride (Midamor), spironolactone (Aldactone), triamterene (Dyrenium).

Combination drugs: amiloride and hydrochlorothiazide (Moduretic); spironolactone and hydrochlorothiazide (Aldactazide); triamterene and hydrochlorothiazide (Dyazide, Maxzide).

See Diuretics: Loop Diuretics and Thiazide Diuretics.

Magnesium deficiency tends to be common among individuals undergoing diuretic therapy, and magnesium supplementation often plays an important role in prevention and treatment of cardiovascular conditions for such patients. According to preliminary

studies involving rats, amiloride has a magnesium-sparing effect in addition to its potassium-sparing effect.[260] Consequently, individuals who take a magnesium supplement while also taking amiloride possibly could theoretically build up excessively high levels of magnesium. Thus the concurrent use of hydrochlorothiazide and amiloride would make this accumulation unlikely given the magnesium-depleting action of hydrochlorothiazide; for example, 5 to 10 mg of amiloride may negate the potassium-wasting effect of 40 mg of furosemide.[5] Nevertheless, Dorup et al.[132] reported that a furosemide-amiloride combination still produced hypomagnesemia in 12% of those treated with such a regimen. Similarly, triamterene may inhibit the urinary excretion of magnesium, according to preliminary research in animals. Initial assessment and regular monitoring of renal function and magnesium status are important to appropriate clinical management of individuals being administered both a potassium-sparing diuretic and a magnesium supplement.

Sulfamethoxazole and Related Sulfonamide Antibiotics

Sulfamethoxazole (Gantanol).
Related: Sodium sulfacetamide (AK-Sulf, Bleph-10, Sodium Sulamyd), sulfanilamide (AVC), sulfasalazine (Salazosulfapyridine, salicylazosulfapyridine, suphasalazine; Apo-Sulfasalazine, Azulfidine, Azulfidine EN-Tabs, PMS-Sulfasalazine, Salazopyrin, Salazopyrin EN-Tabs, SAS), sulfisoxazole (Gantrisin); combination drug: sulfamethoxazole and trimethoprim (cotrimoxazole, co-trimoxazole, SXT, TMP-SMX, TMP-sulfa; Bactrim, Bactrim DS, Cotrim, Septra, Septra DS, Sulfatrim, Uroplus); triple sulfa (Sultrin Triple Sulfa).

Sulfonamides, including sulfamethoxazole, can decrease absorption of magnesium, as well as of calcium and vitamin B_{12}. Although this potential depletion patterns may not be clinically significant when prescribing sulfamethoxazole for less than 2 weeks, physicians prescribing the medication for longer than 2 weeks are advised to monitor magnesium status and supplement when indicated.

RELATED INTERACTION ISSUES

Antacids containing magnesium are involved in many well-known and clinically significant interactions. In such uses, magnesium functions as part of a pharmaceutical agent that, although often self-prescribed and available without a prescription, does not function as a nutrient. Thus, such substances will be treated as drugs rather than nutrients based on their drug class, mechanism of action, therapeutic intent, and commercial channels of distribution and will not be addressed as nutrient-drug interactions.

The more soluble (i.e., better absorbed) chelates of magnesium probably have less influence on absorption of drugs and other compounds. Some research suggests that drug-magnesium complexes may actually be better absorbed and increase bioavailability of both agents. As always, titration of any medication, as well as regular monitoring of electrolyte status, including magnesium and potassium, is essential to safe and effective implementation of integrative therapeutics.

NUTRIENT-NUTRIENT INTERACTIONS

Alcohol

High alcohol intake increases renal excretion of magnesium, and hypomagnesemia is very common in alcoholics (e.g., 30% of alcoholic patients admitted to hospital care).

Calcium

Magnesium intake from food and supplements is associated with bone mineral density.[270] However, high calcium intake may inhibit magnesium absorption. Such competition does not appear to exert a significant effect on overall magnesium status.[271-273] Calcium supplementation, as well as cessation of magnesium administration, is typically used in treating hypermagnesemia.

Iron

Numerous in vitro, animal, and human studies have raised the issue of interactions between magnesium and iron.[159,274] In a clinical trial involving 111 healthy women ages 18 to 40 years, of whom 45 were either iron deficient or iron deplete, Newhouse et al.[275] observed that although therapeutic iron dose (320 mg elemental iron daily as Slow-Fe tablets) for 12 weeks was successful in raising mean serum ferritin values and did not significantly effect serum zinc and magnesium levels during the supplementation period, there was a downward trend through the discontinuation phase; at 18 and 24 weeks, serum zinc and magnesium levels were significantly lower than baseline. These researchers also noted that oral contraceptive use was associated with elevated serum copper and ferritin values and lowered serum magnesium levels.

Rodent studies, single-dose experiments using healthy subjects, and a clinical trial involving two groups of pregnant women with moderately reduced hemoglobin levels showed that concomitant iron gluconate and magnesium-L-aspartate hydrochloride were well tolerated, stabilized hemoglobin levels, and moderated progesterone-induced constipation (during pregnancy), without interfering with iron absorption.[276]

Manganese

Individuals supplementing with manganese may need concomitant supplemental magnesium.

Phosphate

Individuals with high phosphorus intake may experience decreased magnesium absorption. After oral administration, magnesium and other divalent cations can bind to oral phosphate in the GI tract, reducing bioavailability and therapeutic effect of both substances.[6,277] This interaction can usually be avoided by separating oral intake of the two substances by 2 hours. Increased dosage of magnesium may also be medically appropriate for preventive or therapeutic purposes in some individuals.

Potassium

Potassium and magnesium deficiency often occur together and need to be treated concomitantly.[3,101,104,127,129] For example, magnesium (and sometimes sodium) supplementation often needs to accompany potassium supplementation to correct intracellular potassium depletion in hypertensive patients who develop ventricular ectopy and other potassium deficiency effects subsequent to diuretic therapy.[105] However, some research shows that such coadministration may not provide efficacy beyond that of potassium alone in the treatment of some conditions, such as ventricular extrasystoles.[278] Most individuals who benefit from magnesium supplementation also often benefit from potassium supplementation or increased dietary potassium intake. Initial assessment and regular monitoring of renal function and potassium status are important to safe and effective administration of both minerals. Clinically effective levels of potassium require a physician's prescription. A diet rich in fruits, vegetables, and whole grains provides several grams of potassium daily.

Vitamin B_1 (Thiamine)

One case report described a patient in whom cardiac beriberi with polyneuritis developed after protracted use of large amounts of magnesium trisilicate,[279] a poorly absorbable form of magnesium never used as a nutrient, but sometimes used in combination with other mineral salts as a laxative, and widely used as a flowing agent in the tableting and food industries.

Vitamin B_6 (Pyridoxine)

Pyridoxine is necessary for cellular accumulation of magnesium (and zinc), and its presence increases the amount of magnesium that can enter cells. Concurrent administration of both nutrients may enhance therapeutic efficacy.

Vitamin D

Magnesium bioavailability appears to be enhanced by vitamin D.

Zinc

Supplementation with zinc may increase magnesium intake needs, possibly through an inhibitory effect on magnesium absorption and adverse effect on magnesium metabolic balance.[277]

The 279 citations for this monograph, as well as additional reference literature, are located under Magnesium on the CD at the back of the book.

Potassium

Nutrient Name: Potassium.
Synonym: Kali.
Elemental Symbol: K.
Forms: Potassium aspartate, potassium bicarbonate, potassium chloride, potassium citrate, potassium gluconate, potassium iodide, potassium-R-lipoate, potassium orotate, potassium para-aminobenzoate.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Albuterol, ritrodrine Beta-2-adrenoceptor agonist bronchodilators ≈≈/○	Oral or intravenous albuterol, ritrodrine, and related beta-2-adrenoceptor agonists can deplete potassium and other nutrients, possibly to a clinically significant degree. Hypokalemia due to these drugs, particularly in combination with steroids or digoxin, may contribute to arrhythmias or aggravate asthma. Evidence is lacking to determine frequency of occurrence or confirm benefits of potassium coadministration.	Monitor regularly. Coadministration of potassium (and magnesium) may prevent or correct nutrient depletion.
Amiloride Antikaluretic-diuretic agent ✗✗/✗✗✗/◇◇	As a potassium-sparing diuretic, amiloride carries implicit risk of hyperkalemia when combined with significant increase in potassium intake, especially with compromised renal function and concomitant ACE inhibitor therapy. Probability of adverse events with concurrent use of potassium supplements, salt substitutes, or food sources generally recognized; risk of acute and severe event with rapid increase in intake.	Limit potassium intake, and avoid rapid and significantly increased intake, outside professional supervision. Closely monitor high-risk patients.
Aminoglycoside antibiotics ≈≈/○	Aminoglycosides can cause renal tubular damage and induce hypokalemia; renal failure is also potentiated by potassium depletion. Case reports and animal studies available; small but recognized risk for elderly and compromised persons. Evidence from clinical trials lacking to confirm benefits of concomitant potassium.	Concurrent potassium may prevent or correct adverse effects with long-term or repeated drug therapy. Monitor.
Amphotericin B ≈≈/○	Amphotericin can cause potassium depletion, especially with steroids; hypokalemia is possible, particularly with drug-induced renal damage or rapid infusion. Not common but widely recognized.	Concurrent potassium may prevent or correct adverse effects with long-term or repeated drug therapy. Monitor.
Angiotensin-converting enzyme (ACE) inhibitors ✗✗/✗✗✗/◇◇	Significant risk of hyperkalemia when potassium intake increased during ACE inhibitor therapy, especially with compromised renal function or diabetes. Probability of acute and severe adverse events with concurrent use of potassium supplements, salt substitutes, or food sources generally recognized, particularly with rapid increase in intake.	Limit potassium intake, and avoid rapid and significantly increased intake, outside professional supervision. Closely monitor high-risk patients.
Beta-adrenoceptor antagonists ✗✗/✗✗✗	Beta blockers can elevate potassium levels and may cause hyperkalemia. A variety of mechanisms may be involved, but not fully elucidated. Frequency unknown, but potentially severe consequences.	Potassium generally contraindicated but may be indicated in certain circumstances. Monitor potassium closely with beta blockers.
Carbonic anhydrase inhibitors ≈≈	Carbonic anhydrase inhibitors generally decrease renal blood flow and glomerular filtration rate. However, other than furosemide and acetazolamide, limited evidence indicates they do not appear to affect potassium status adversely in most individuals. Potential for significant disequilibrium in carbon dioxide transport; low probability but high risk.	Concurrent potassium may prevent or correct adverse effects with long-term or repeated drug therapy. Monitor, especially for acidosis.
Cisplatin ≈≈/⊕✗/✗✗	Renotubular damage is common with cisplatin and may cause wasting of potassium and other minerals. Resulting hypokalemia may be refractory without concomitant administration of potassium and magnesium. Risk of clinically significant adverse effects widely recognized.	Concurrent potassium and magnesium may prevent or correct depletion. Protect renal function. Closely monitor electrolyte status.
Colchicine ◇≈≈	Colchicine can impair absorption and increase loss of potassium (and other nutrients). Coadministration of potassium may prevent or correct clinically significant adverse effects. Minimal research but widely accepted as possible or probable.	Coadministration of potassium and other nutrients may prevent or correct adverse effects with long-term or repeated drug therapy. Monitor.
Corticosteroids, oral ≈≈/○	Oral corticosteroids can deplete potassium and other nutrients, possibly to clinically significant degree. Hypokalemia due to these drugs, particularly in combination with other agents affecting potassium status, may contribute to edema, arrhythmias, or aggravate asthma. Widely recognized, but minimal evidence and lack of consensus as to clinical significance. Benefits of potassium coadministration unproven.	Consider coadministration of potassium and other nutrients, may prevent or correct adverse effects with long-term therapy. Monitor, especially with renal impairment.
Cyclosporine ◇◇	Cyclosporine-induced nephrotoxicity and other mechanisms can cause hyperkalemia, most often in patients with compromised renal function. Onset of effects can be rapid or gradual. Varied attempts at reducing drug toxicity and its effects on renal function and potassium metabolism, but mixed results and no consensus as to effective corrective measures.	Close monitoring of allograft patients is always essential. Potassium generally contraindicated, but coadministration may be indicated; caution imperative.

Continued

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Digoxin Cardiac glycosides ◇≈≈/⊕✗	Hypokalemia increases risk of digoxin toxicity, but digoxin impairs potassium function, and overdose can cause hyperkalemia. Increased risk in patients taking diuretics. Interplay with magnesium; increased risks with dual depletion.	Consider coadministration of potassium, magnesium, and other nutrients, especially through food sources; may prevent or correct adverse effects. Monitor, especially with diuretics and renal impairment.
Diuretics, potassium depleting Loop and thiazide diuretics ≈≈/☼	Potassium-wasting diuretics inherently increase risk of potassium depletion and hypokalemia. Generally accepted as inherent risk of clinically significant adverse effects. Concomitant ACE inhibitor therapy or other polypharmacy often used to mitigate depletion.	Coadministration of potassium and other nutrients, as food or supplements, can prevent or correct depletion and sequelae. Monitor.
Laxatives Stool softeners ≈≈≈/☼	Through various mechanisms, laxatives or stool softeners can deplete potassium and other nutrients, more often with repeated use. However, hypokalemia occasionally possible with short-term cathartic use, as in procedure preparation. Generally recognized as possible risk, but corrective measures inconsistently applied. Increased risk of adverse effects in cardiac patients, especially with concomitant diuretics or other potassium-depleting drugs.	Review diet and exercise; advise improvements as indicated. Coadministration of potassium and other nutrients may prevent or correct adverse effects with long-term or repeated drug therapy. Monitor.
Losartan Angiotensin II receptor antagonists ✗✗/✗✗✗/◇◇	All angiotensin II receptor antagonists inherently carry risk of hyperkalemia. Through effects on renin-angiotensin system and aldosterone, losartan may cause clinically significant elevations in potassium levels. Effect on potassium is universal and widely recognized. However, severity may vary, and clinically significant events are uncommon.	Avoid extra potassium, especially rapid and significantly increased intake, outside professional supervision. Monitor regularly.
Nonsteroidal anti-inflammatory drugs (NSAIDs) ✗✗/✗✗✗/◇◇	Various NSAIDs alter potassium metabolism through a range of mechanisms, many only partially understood, but many resulting from drug-induced nephrotoxicity. Severe potassium-related adverse effects with NSAIDs are uncommon but not rare; they may be acute and reversible, but chronic renal failure possible.	Limit potassium intake, and avoid rapid or significantly increased intake; professional supervision indicated. Closely monitor high-risk patients.
Quinidine Antiarrhythmic drugs ≈≈/☼	Hypokalemia of various origins can significantly increase risk of acute cardiac irregularities and adverse reactions to antiarrhythmic drugs, especially when accompanied by hypomagnesemia.	Closely monitor; restore electrolyte balance, particularly magnesium and potassium, whenever disturbed or depleted by diuretics, vomiting, diarrhea, or other causes.
Spironolactone, triamterene ◇◇/✗✗	Potassium-sparing diuretics (spironolactone, triamterene) carry implicit risk of hyperkalemia if potassium intake significantly increased, especially with compromised renal function or concomitant ACE inhibitor. Probability of acute and severe adverse events with concurrent use of potassium supplements, salt substitutes, or food sources generally recognized. Frequently coadministered with potassium-depleting diuretics based on known activity.	Limit potassium intake, and avoid rapid and significantly increased intake; professional supervision indicated. Closely monitor high-risk patients.
Trimethoprim-sulfamethoxazole ◇◇/✗✗/✗✗✗	Trimethoprim, alone or with sulfamethoxazole, can elevate potassium levels, sometimes causing hyperkalemia, through one or more mechanisms involving renal function. Severe adverse effects are uncommon but not rare; they may be acute and reversible, but chronic renal failure possible. Risk minimal to moderate for most patients but increased in AIDS patients or others with compromised physiological function or polypharmacy affecting renal function.	Limit potassium intake, and avoid rapid or significantly increased intake, outside professional supervision. Closely monitor high-risk patients.

NUTRIENT DESCRIPTION

Chemistry and Forms

Potassium aspartate, potassium bicarbonate, potassium chloride, potassium citrate, potassium gluconate, potassium orotate, potassium tartrate.

Physiology and Function

Cell membrane excitability, ion transport, and energy production are central functions of potassium in human physiology. Potassium, sodium, and chloride are the essential dietary minerals that serve as the major electrolytes in the human body within a triangular equilibrium. Directly and through these relationships, potassium participates in the regulation of water balance, osmotic equilibrium, acid-base balance, and blood pressure, and it plays a critical role in the contractility of smooth, cardiac, and skeletal (striated) muscle, particularly through its contribution to nerve function and carbohydrate and protein metabolism. It participates in glucose metabolism through its involvement with insulin in the movement of blood glucose into cells and conversion of blood glucose into glycogen for storage in the muscles and liver.

Potassium (K^+) is the principal cation in intracellular fluid, whereas sodium (Na^+) is the principal extracellular cation. Potassium concentrations are tightly regulated both inside and outside of cells, with a differential of 30 times, and this sodium-potassium concentration gradient creates the membrane potential on which all contractility and nerve function depend.

Water balance is maintained by using ion pumps in the cell membrane, especially the sodium-potassium-adenosinetriphosphatase (Na^+, K^+-ATPase) pumps, to move potassium into cells in exchange for sodium being pumped out of cells. The proper functioning of nerve impulse transmission, muscle contraction, and cardiac function all require tight control of cell membrane potential. The critical function of these ion pumps is demonstrated in their exchange activities, accounting for 20% to 40% of the resting energy expenditure (of ATP) in a typical adult. The activity of the adenosine triphosphate (ATP)–sensitive K^+ channel plays an important role in mitochondrial cell-signaling pathways for ischemic protection and gene transcription, "roles that appear to depend on the ability of mitochondrial K(ATP) opening to trigger increased mitochondrial production of reactive

oxygen species."[1] Beyond Na^+, K^+-ATPase, potassium is required as a cofactor in the activity of only a few other enzyme systems, such as pyruvate kinase, central to carbohydrate metabolism. Potassium is also essential for proper kidney and adrenal function.

Potassium salts are inherently highly soluble, and dietary potassium intake is readily absorbed, 85% to 98%, principally in the small intestine. Average body content of potassium is 180 grams, and the intracellular fluid holds approximately 98% of the total body potassium. Dietary potassium is primarily excreted in the urine (~ 77%-90%), with minimal renal capacity for conservation and minimal elimination of unabsorbed and intestinally secreted potassium eliminated via feces. The correlation between dietary potassium intake and urinary potassium content is high ($r = 0.82$). Small amounts of potassium are excreted, along with other electrolytes, through perspiration and saliva.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Potassium is among the nutrients more frequently prescribed in conventional medical practice, particularly in the context of hypertension and drug-induced depletion, as well as diarrhea and other causes of acute electrolyte depletion or disequilibrium. Although the legal limitation of potassium in over-the-counter (OTC) preparations to 99 mg in the United States is unique, much higher dosage levels are often prescribed in conjunction with potassium-wasting diuretics, or simply are attainable through consumption of a few pieces of fruit daily (or many electrolyte-rich "sports" drinks). Professional supervision and regular monitoring of serum potassium concentrations are appropriate whenever potassium is coadministered with conventional medications. Notably, perioperative outcomes are better in cardiac surgery patients with adequate potassium levels than those in patients with low preoperative serum potassium levels, who are at increased risk of developing arrhythmias and more likely to require cardiopulmonary resuscitation.[2] Conversely, hyperkalemia can occur when excess potassium accumulates because of decreased urinary potassium excretion as a result of diminished renal elimination, or more rarely, acute excessive intake. Apart from unintended effects of potassium-sparing diuretics, acute or chronic renal failure and hypoaldosteronism constitute the most common causes of hyperkalemia. Hemolysis, traumatic tissue damage, severe burns, and tumor lysis syndrome may also produce hyperkalemia as a result of a rapid shift of intracellular potassium into general circulation.

Historical/Ethnomedicine Precedent

The simple admonition to eat plenty of fruits and vegetables, especially those grown in soil rich with minerals, represents a time-honored recommendation that would encompass a healthful dietary potassium intake.

Possible Uses

Allergies, asthma, atherosclerosis, cancer, cardiac arrhythmia, congestive heart failure, Crohn's disease, diabetes mellitus (mild), diarrhea (especially in infants), electrolyte depletion, glaucoma, hypertension, hypokalemia, inflammatory bowel disease, muscle cramping and spasms, muscle fatigue and weakness, nephrolithiasis, osteoporosis, premenstrual syndrome, stroke, ulcerative colitis.

Deficiency Symptoms

Potassium deficiency can lead to a broad range of adverse effects across multiple body systems. These effects primarily derive from alterations in membrane potential and cellular metabolism and include muscle weakness, fatigue, listlessness, irritability, apprehension, mental confusion, drowsiness, nerve conduction irregularities, respiratory failure, reduced or absent reflexes, paralysis, cardiac disturbances (particularly arrhythmia), hypotension, muscle cramping and spasms, anorexia, nausea, abdominal bloating, delayed gastric emptying, constipation, paralytic ileus, polydypsia, and polyuria. Severe hypokalemia can be fatal as a result of cardiac arrhythmias and muscular paralysis. Electrocardiographic (ECG) changes accompanying hypokalemia are ST depression, flat T waves, U waves, and dysrhythmias. The pulse will alternate between fast and slow. It is necessary to monitor for digitalis toxicity in digitalized patients.

Most incidents of hypokalemia (i.e., abnormally low plasma potassium concentration) result from excessive loss of potassium, but inadequate or unbalanced intake can make a significant contribution. Thus, gross deficiencies of potassium are most often associated with use of potassium-depleting diuretics or glucocorticoids but can also result from severe or prolonged vomiting, diarrhea or perspiration, gastrointestinal (GI) disturbances caused by parasites, ostomy, laxative abuse or food reactions, some forms of renal disease, or other metabolic disturbances (e.g., acidosis) associated with alcoholism, anorexia nervosa, bulimia, rapid weight loss, congestive heart failure, chronic obstructive pulmonary disease, diabetes mellitus, or magnesium depletion. To a lesser degree, because potassium losses increase with perspiration, exercise and heat exposure, particularly hot humid climate, can adversely affect potassium status. In another clinical scenario, fluid shifting from the extracellular to the intracellular fluid compartment as a result of elevated insulin levels in the treatment of diabetic ketoacidosis is the most common cause of a drop in serum potassium levels. Subsequently, potassium is pulled from the intracellular space to the serum and then excreted through the kidneys in the hyperglycemic phase. At that point, serum potassium levels appear elevated, even though the stores are being lost with polyuria. Consequently, in the absence of replacement, serum potassium can drop to dangerously low levels if insulin is administered to reduce the hyperglycemia and potassium returns to the intracellular space. In a less dramatic process, potassium can become depleted during periods of stress as the adrenal glands secrete increased levels of adrenaline, which pulls potassium from the cells to be lost by the kidneys' excretion. Similarly, overproduction of corticosteroids resulting from Cushing's syndrome, hyperaldosteronism, or other endocrine disorders (or exogenous administration) can provoke sodium retention and increase potassium excretion.

Absolute potassium deficiency is relatively rare, but relative potassium deficiency (i.e., in relation to sodium excess) is common, even in those with apparently healthy diets. In 2001 the Third National Health and Nutrition Examination Survey (NHANES-III) found that the modern American diet, especially when dominated by salt and processed foods, contains an average of 2300 mg of potassium daily for adult females and 3100 mg daily for adult males; slightly more than minimum daily requirements but approximately one-quarter to one-third the estimated daily potassium intake of hunter-gatherers or other "primitive" diets. Moreover, with daily potassium intake in modern diets being half as much as the typical daily sodium intake, most experts recommend significantly higher levels of dietary potassium, for

example, a ratio of at least 5:1 or optimally 10:1 potassium/sodium intake or more, especially in the form of fresh fruits and vegetables. Dietary intake for reducing risk of hypertension, heart disease, and stroke is at least in the range of 4 to 5 g daily. Thus, even though low dietary intakes of potassium will generally not produce hypokalemia, insufficient dietary potassium probably increases significantly the risk of a wide range of chronic diseases, especially in the context of an imbalanced or poor-quality diet.

Several commonly consumed substances may induce lowered potassium levels. Caffeine and tobacco can reduce potassium absorption. Apart from the major adverse impact on potassium status associated with sodium intake, magnesium can also cause increased excretion of potassium in the stool with excess intake. Rare case reports describe hypokalemia subsequent to continued intake of large doses of licorice; the herb (but usually not the candy) contains glycyrrhizic acid, which can increase urinary excretion of potassium in a manner similar to aldosterone.

Dietary Sources

Fruits and vegetables are generally the richest dietary sources of potassium, and an individual who eats a diet high in these can have a high potassium intake (8-11 g/day). Notably, however, U.S. Department of Agriculture (USDA) data (2004) documented changes in food composition for 43 garden crops indicating that the nutrient content of many vegetables and fruits declined significantly from 1950 to 1999.[3]

Bananas, orange juice, prunes and prune juice, raisins, avocados, cantaloupes, peaches, tomato juice, potatoes (baked with skin), soy flour, white beans, lima beans (cooked), lentils (cooked), acorn squash (cooked), parsnips (cooked), turnips (cooked), artichokes (cooked), and spinach (cooked) contain more than 300 mg of potassium per serving. Other foods providing moderate amounts of potassium include oranges, tomatoes, other fruits and vegetables, mint leaves, molasses, whole grains, sunflower seeds, almonds, flounder, salmon, cod, milk, chicken, and red meat.

Common herbs also considered sources of potassium include red clover, sage, catnip, hops, horsetail, nettle, plantain, and skullcap.

The potassium/sodium ratio in foods varies considerably and is more influential than the potassium content per se. Beans, peas, potatoes, grains, nuts, and fruits are among the foods with the highest potassium/sodium ratio. Thus, bananas or navy beans contain more than 1000 times more potassium than sodium, and Brazil nuts or corn contain more than 700 times more potassium than sodium. In comparison, eggs, beef, and fish contain 6 to 10 times more potassium than sodium, and spinach, celery, and beets contain only about 2.5 to 4 times more potassium than sodium, as do whole milk, chicken, and lamb. Many health care professionals advise using potassium chloride, rather than sodium chloride, as a seasoning to shift the potassium/sodium balance.

Nutrient Preparations Available

Potassium preparations can be potassium salts (chloride and bicarbonate), potassium bound to various mineral chelates (e.g., aspartate, citrate), or food-based potassium sources. Forms of potassium used as supplemental nutrients or as pharmaceutical agents include potassium aspartate, potassium bicarbonate, potassium chloride (oral, effervescent, or injection), potassium citrate, potassium gluconate, potassium iodide (oral solution or syrup), potassium-R-lipoate, potassium orotate, and potassium para-aminobenzoate. Potassium gluconate and potassium citrate are the most common supplemental forms. Potassium is administered parenterally when oral replacement is not possible or if hypokalemia is life threatening. Intravenous (IV) administration without cardiac monitoring should not exceed 10 mEq/hr.

Available forms are composed of potassium bound to other nonmetallic substances that render it chemically stable. Pure potassium is never available as a supplement or prescription item because it is a highly reactive metal that spontaneously ignites when exposed to water. Potassium bicarbonate or citrate is the form most conducive to a reduced risk of kidney stones.[4,5] Among the chelated forms used orally, potassium citrate is generally better tolerated (and possibly more efficacious), whereas potassium chloride is less well tolerated, although it is used as a substitute for table salt and, in solution, for IV administration. A large amount given rapidly after sedation and neuromuscular paralysis is used as part of execution by lethal injection because it stops cardiac electrical activity and thus cardiac function.

Prescription preparations of potassium usually contain an inorganic form of potassium, usually potassium chloride, along with nonnutritive additives, and are dispensed as timed-release tablets, liquids, powders, and effervescent tablets, typically in the dosage range of 1.5 to 3 g (20-40 mEq) daily. Potassium iodide is also the preferred agent recommended by some governmental bodies as a protective measure against iodine-131 radiation-induced thyroid cancer in cases of nuclear radiation contamination.

Potassium is available generically from numerous manufacturers as an over-the-counter (OTC) product, but it is limited to 99 mg per serving as a nutritional supplement, which is small compared with the U.S. Institute of Medicine's recommendation for a dietary intake of 4700 mg daily. More significant quantities of supplemental potassium require a physician's prescription. Notably, so-called salt substitutes, such as Morton Salt Substitute, Lite Salt, No Salt, and Nu-Salt, are basically potassium chloride at the dosage level of 530 mg of potassium per ¼ teaspoon.

Dosage Forms Available

Divided doses, taken with or near food, throughout the day are generally best for availability and tolerance.

Over-the-counter potassium supplements, singly or within multivitamin/mineral formulations, typically contain 99 mg of potassium per recommended daily dose, the legal nonprescription limit in the United States, as established by the Food and Drug Administration (FDA), for non-food-based forms. Notably, so-called salt substitutes, such as Morton Salt Substitute, Lite Salt, No Salt, and Nu-Salt, are basically potassium chloride at the dosage level of 530 mg potassium per ¼ tsp.

Dosage Range

Adult

Dietary: A daily intake of 2000 mg (51 mEq) is generally considered an adequate (i.e., minimum) requirement of potassium for adult men and women, including for pregnant and nursing women. The need to ensure a (minimal) daily potassium intake of 2.5 to 3.5 g, a supply from fruits and vegetables (chiefly as citrate or malate, through daily intake of 0.6-0.8 mg/kg) represents the underlying rationale for the often-repeated "5 to 10 servings per day" recommendations from official bodies. Many practitioners experienced in nutritional medicine recommend 6 to 9 g from food sources as an optimal daily intake.

In 2004 the Food and Nutrition Board (FNB) of the U.S. Institute of Medicine established, for the first time, a recommended adequate intake (AI) level of 4700 mg (120 mEq) per day of potassium for adult, based on intake levels that have been found to lower blood pressure, reduce salt sensitivity (particularly in African-American men), and minimize the risk of kidney stones. However, the AI for potassium during lactation is set at 5100 mg (130 mEq)/day (4700 + 400 mg).[6] In the United Kingdom the average adult daily diet provides 2562 mg for women and 3279 mg for men.

Supplemental/Maintenance: No dosage level has been officially established for use as a dietary supplement. Potassium supplementation is not normally necessary in the presence of a balanced diet.

Pharmacological/Therapeutic: An oral dose of 1500 to 4000 mg daily, with plenty of fluid, is usually indicated in correction of mild deficiency or to lower blood pressure. More broadly, therapeutic doses can range from 100 to 6000 mg per day.

As a prescription medication, potassium is usually measured according to milliequivalents (mEq) or millimoles (mmol) rather than as milligrams (mg). To convert mg of elemental potassium to mEq, take mg and divide it by 39.0983 (atomic weight of potassium). For example, 90 mg is equivalent to 2.30 mEq, and 99 mg is equivalent to 2.53 mEq. Conversely, if you know the mEq, multiply by 39.0983 to find the elemental potassium weight in mg. For example, 2 mEq is equal to 78.0 mg. A typical therapeutic dosage of potassium is between 10 and 20 mEq, three to four times daily; professional supervision is recommended.

Toxic: Daily intakes exceeding 17 g, difficult to obtain from oral supplements, would be required to produce potassium toxicity. Hyperkalemia from oral administration is virtually unknown in individuals with normal renal function. Thus, the U.S. FNB noted that in "otherwise healthy individuals (i.e., individuals without impaired urinary potassium excretion from a medical condition or drug therapy), there is no evidence that a high level of potassium from foods has adverse effects," and concluded that "a Tolerable Upper Intake Level (UL) for potassium from foods is not set for healthy adults."[6]

Pediatric (<18 Years)

Dietary: As of 2004, official U.S. recommendations for AI were established for the first time[6]:

Children, 1 to 3 years: 3000 mg (77 mEq)/day
Children, 4 to 8 years: 3800 mg (97 mEq)/day
Children, 9 to 13 years: 4500 mg (115 mEq)/day
Children, 14 to 18 years: 4700 mg (120 mEq)/day

Supplemental/Maintenance: Usually not recommended for children under 12 years of age with healthy, balanced diet.
Pharmacological/Therapeutic: Not established.
Toxic: Not established.

Laboratory Values

The accuracy of laboratory assessment of potassium status is severely limited because most potassium in the human body is within cells. Consequently, measuring levels of free potassium in the serum will only detect deficiency in extreme depletion states. Measurement of potassium levels in red blood cells (RBCs), white blood cells (WBCs), or other intracellular tissues can provide a more accurate index of tissue potassium stores and thus reveal potassium insufficiency more readily.

Serum Potassium (K^+)

Normal levels are 3.5 to 5.0 mmol/L. (To convert mg of elemental potassium to mEq, take mg and divide it by 39.0983 [atomic weight of potassium].) Low serum potassium levels may reflect a shift to intracellular space or to depletion from the total body stores. Hyperkalemia is indicated by an increase in the serum potassium concentration above 5.5 mEq/L (plasma potassium >5.0).

Urinary Potassium (24 Hour)

Normal levels are 26 to 123 mmol/day.

Ranges depend on dietary intake. Because potassium excretion in the urine varies with intake and concentrations are affected by fluid intake, 24-hour measurement of urinary potassium provides a more consistent value.

Erythrocyte Potassium

Normal levels are approximately 100 mmol/L RBCs. This test most accurately reflects tissue stores.

Note: *Pseudohyperkalemia* is defined as a difference between serum and plasma potassium greater than 0.4 mmol/L. Cases have been reported in which potassium is released from platelets, WBCs, or RBCs into the serum as blood clots, giving a falsely high value. This has occurred in polycythemia rubra vera, other myeloproliferative disorders with a high hematocrit or high platelet count, release of potassium from platelets during coagulation, RBC hemolysis during or after collection, and a protracted interval between blood sampling and separation of serum. Such misleading findings can be avoided, and a more accurate estimation obtained, by use of plasma instead of serum.[7]

SAFETY PROFILE

Overview

At moderate or high dosage levels, potassium salts taken orally can cause symptoms of nausea, vomiting, abdominal discomfort, diarrhea, and ulcers. A single dose of several hundred milligrams in tablet form can produce gastric irritation, especially when ingested on an empty stomach, with potassium chloride particularly well known for adverse effects, even in liquid forms. Microencapsulated forms are generally better tolerated. In contrast, modified-release preparations (e.g., potassium chloride with enteric coating) have been associated with GI ulceration. Adverse effects can usually be prevented or reduced by taking potassium with meals. Potassium in dietary forms, at any intake level, is generally not associated with adverse effects, except that occasionally, ingestion of potassium-rich fruit has been reported to produce hyperkalemia in the context of potassium-sparing diuretics and ACE inhibitor medications. Most adverse effects associated with potassium result from depletion and deficiency. Chronic renal insufficiency requires dietary restriction of potassium (and magnesium) with careful monitoring of blood levels.

Nutrient Adverse Effects

Gastrointestinal (GI) symptoms constitute the most common adverse effects associated with nondietary potassium intake, with nausea, vomiting, abdominal discomfort, and diarrhea quite common and ulceration less frequent. When indicated, high-potency potassium chloride tablets should only be administered in a slow-release form (e.g., Slow K), to minimize the risk of GI distress or bleeding ulcers often attributable to the high amounts of chloride in the tablets.

The most serious adverse reaction to potassium is hyperkalemia. Abnormally elevated serum potassium concentrations [K^+] occur when potassium intake exceeds the capacity of renal elimination. The accumulation of excess potassium can occur with decreased urinary potassium excretion due to acute or chronic renal failure, hypoaldosteronism, or the use of potassium-sparing diuretics, ACE inhibitors, or other drugs. More acutely, a shift of intracellular potassium into the circulation, most often resulting from hemolysis or sudden tissue damage, can also cause hyperkalemia. Thus, hyperkalemia is almost always caused by metabolic derangement due to pathophysiology (especially compromised kidney function) or medications that interfere with metabolic feedback systems; close monitoring is always appropriate when treating such patients.

A toxic reaction with severe hyperkalemia could potentially result from rapid ingestion of oral doses greater than 17 g (434 mEq) by individuals not acclimated to high intake, even with normal renal function.[6] Ingestion of a dose this size would be difficult and unlikely to occur unintentionally.

Potassium is generally considered to be neither a mutagen nor a carcinogen in standard forms at typical doses.

Adverse Effects Among Specific Populations

Individuals with compromised renal function, especially chronic renal failure, are at greatest risk for complications.

Pregnancy and Nursing

Specific data on potassium administration or supplementation in pregnancy and nursing are lacking. However, typical supplemental dosage levels are at or below recommended dietary intake levels or doses from typical intake of many common (and healthful) foods.

Infants and Children

Specific data on potassium administration or supplementation in infants and children are lacking. However, typical supplemental dosage levels would be at or below recommended dietary intake levels or doses from typical intake of many common (and healthful) foods.

Contraindications

Limited risk with food-level doses, but excessive doses should be avoided outside professional supervision and close monitoring: Addison's disease; compromised renal function, especially chronic renal failure; heart block; peptic ulcer; GI ulceration or obstruction; acute dehydration; severe burns.

Precautions and Warnings

Concurrent medications that alter potassium metabolism or interfere with potassium regulation, except with supervision and monitoring, including amiloride, spironolactone, triamterene, or other potassium-sparing diuretics, and ACE inhibitors such as captopril, enalapril, or lisinopril. Note that in such cases, consumption of foods providing potassium at recommended level (4.5–4.7 g/day) may develop excessive potassium levels. Caution also warranted in individuals undergoing trimethoprim-sulfamethoxazole therapy.

The 2004 recommendations from the U.S. FNB state: "Overall, because of the concern for hyperkalemia and resultant arrhythmias that might be life-threatening, the proposed AI [Adequate Intake: 4700 mg per day for adults] should not be applied to individuals with chronic kidney disease, heart failure, or type 1 diabetes, especially those who concomitantly use ACE inhibitor therapy. Among otherwise healthy individuals with hypertension on ACE inhibitor therapy, the AI should apply as long as renal function is unimpaired."[6]

INTERACTIONS REVIEW

Strategic Considerations

A cursory review of standard information on the therapeutic applications, effects and risks, interactions, and depletion patterns associated with potassium typically focuses on hypertension, diabetes, and renal disease, or frank hypokalemia/hyperkalemia, often to the exclusion of the diverse effects of numerous medications on the key physiological functions of potassium and its many clinical applications. A deeper and broader review of the scientific literature looking at therapeutic applications beyond mere "supplementation" reveals both subtle and profound, gradual and rapid, obvious and complex effects of potassium insufficiency, deficiency, or excess, even when not necessarily at the threshold of hypokalemia or hyperkalemia. Health care professionals applying the information available through such an integrative analysis can discover many opportunities for enriching their therapeutic repertoire and enhancing clinical outcomes while avoiding or carefully navigating some of the more problematic encounters between potassium and various drugs, particularly in the context of treating patients with chronic disease or metabolic maladaption.

Potassium is one of the primary mineral nutrients, which, along with magnesium, are the most susceptible to drug-induced depletion. Such depletion patterns, particularly in early stages, are typically difficult to detect at the intracellular level, where hypokalemia can be most significant, especially for normal cardiac muscle and electrical activity. Potassium-wasting diuretics, particularly the thiazide and loop diuretics, represent the most widely recognized examples of medications that inherently increase risks of potassium depletion and hypokalemia. However, long-term, repeated, and high-dose use of numerous pharmaceutical agents, such as beta-2-adrenoceptor agonists, colchicine, amphotericin B, and laxatives or stool softeners, can impair potassium absorption, deplete potassium, and interfere with its physiological activity. Hypokalemia resulting from these drugs, particularly in combination with steroids or digoxin, may contribute to edema, acute cardiac rhythm irregularities, aggravation of asthma, or other adverse responses. Compensatory increase in potassium intake can usually, but not always, prevent or correct drug-induced adverse effects, and sometimes the corrective remedy is simply regular intake of several pieces of potassium-rich fruit. However, in situations such as cyclosporine-induced nephrotoxicity and hyperkalemia, adverse effects can be either rapid or gradual in onset, and attempts at mitigating drug toxicity through nutrient support can be of limited effectiveness. Likewise, the risks accompanying diuretic therapy or renal impairment can become unpredictable and complex, especially when interacting with agents such as digoxin, which can intrinsically impair potassium function; digoxin toxicity increases with hypokalemia, and digoxin overdose can cause hyperkalemia. In this case, as in many others, the intimate relationship between potassium and magnesium (as well as other key nutrients) reveals itself in physiology, therapeutics, interactions, and parallel depletion patterns and demonstrates the need for a comprehensive risk assessment and nutrient support strategy. As with many drug-induced depletion patterns, evidence of benefit from nutrient coadministration is often present in clinical practice but lacking in the scientific literature. Close monitoring is imperative in patients with intertwined pathologies,

multiple medications, and comorbidities such as renal impairment, cardiac conditions, organ allografts, or other complicating factors.

Serum/plasma concentrations indicate critical deficiency or excess and disequilibrium or dysregulation, but potassium depletion at the intracellular level is difficult to detect with conventional laboratory assessment of blood constituents. Increasing potassium intake with potassium-rich foods, salt substitutes, and supplements is generally indicated and effective, although increased vigilance is necessary in the setting of compromised renal function or other medications altering potassium status.

Mineral wasting caused by renal tubular damage occurs in patients being treated with cisplatin or aminoglycosides, particularly in elderly and compromised populations, and hypokalemia often results. potassium depletion can further potentiate renal insufficiency or failure in such cases. Concurrent potassium therapy may prevent or correct adverse effects with long-term or repeated drug therapy, but evidence is limited. With cisplatin, however, refractory hypokalemia may require concomitant administration of both potassium and magnesium, possibly because of the magnesium dependence of the Na^+,K^+-ATPase membrane "pump" enzyme. Some agents, such as carbonic anhydrase inhibitors, can decrease renal blood flow and glomerular filtration rate. However, other than furosemide and acetazolamide, these may not adversely impact potassium status in most individuals. Nevertheless, given the potential for significant disequilibrium in carbon dioxide and bicarbonate transport, risks may be significantly elevated in certain individuals.

Hypokalemia, whether from disease, drugs, or physiological degeneration, can increase risks associated with many pharmaceutical agents that require stable levels of potassium and other key nutrients. For example, hypokalemia of various origins can significantly increase risk of acute cardiac rhythm irregularities and adverse reactions to quinidine and other antiarrhythmic drugs, especially when accompanied by hypomagnesemia.

Certain medications lead to increased potassium levels and potential for hyperkalemia, with the attendant risk of severe adverse events, sometimes acute, often chronic. Notably, hyperkalemia was virtually unknown except in renal failure until introduction of several drug classes in recent years. This rapid escalation of occurrence of hyperkalemia represents a major challenge in the chronic care of patients with multiple intertwined and complex patterns of dysfunction and disease, debilitation, and comedication.

In the context of certain medical conditions and comedications, some drugs can create or aggravate a risk of hyperkalemia and the potential for sudden onset of severe symptoms. Amiloride or other potassium-sparing diuretics carry an implicit risk of hyperkalemia when combined with a significant increase in potassium intake, especially with compromised renal function and concomitant ACE inhibitor therapy. Likewise, beta-adrenergic blockers can also elevate potassium levels and cause hyperkalemia through uncertain and often unpredictable mechanisms. Similarly, losartan and other angiotensin II receptor antagonists inherently carry a risk of hyperkalemia.

In these cases, potassium intake needs to be limited and patients educated as to the various sources (and relative dosages) of potassium. Some medications, such as trimethoprim, alone or in combination with sulfamethoxazole, can elevate potassium levels and may occasionally cause hyperkalemia, usually through effects on renal function; although uncommon and often reversible, severe adverse effects can be acute, and renal failure is possible. High-risk patients, such as those with compromised physiological function, with human immunodeficiency virus (HIV) infection, or receiving polypharmacy affecting renal function, should always be monitored closely. Perhaps more importantly than any absolute prohibition, patients need to avoid rapid or significantly increased potassium intake (e.g., new use of salt substitute) outside professional supervision.

As a mineral, potassium has variable risk for pharamacokinetic interference in which binding between the drug and potassium impairs biovailability and decreases therapeutic effect of both agents. Risks of clinically significant adverse effects are generally minimized by separating oral intake by several hours.

In a few cases, administration of potassium is relatively contraindicated in patients with specific pathological conditions or being treated with specific medications. Nevertheless, such contraindication is often cautionary, and coadministration of these agents is safe, or even beneficial in certain patients, but requires regular monitoring and close supervision by health care professionals trained and experienced in the various modalities and their integrative application.

NUTRIENT-DRUG INTERACTIONS

Albuterol/Salbutamol, Rimiterol, and Related Beta-2-Adrenoceptor Agonists

Evidence: Intramuscular (IM), intravenous (IV), and subcutaneous (SC) forms: Albuterol (salbutamol), rimiterol (Pulmadil).
Extrapolated, based on similar properties: IM, IV, and SC forms: Fenoterol (Berotec), isoetharine (Arm-A-Med, Bronkosol, Bronkometer), pirbuterol (Exirel), salmeterol, tulobuterol (Brelomax).
Similar properties but evidence indicating no or reduced interaction effects: Inhalation forms: Albuterol (Albuterol Inhaled, Proventil, Ventolin); combination drug: albuterol and ipratropium bromide (Combivent); isoporterenol (isoprenaline; Isuprel, Medihaler-Iso), levalbuterol (Xopenex), metaproterenol (Alupent), salmeterol (Serevent, combination drug: Advair), terbutaline (Brethaire, Brethine, Bricanyl).

Effect and Mechanism of Action
Albuterol, administered by IM, IV, and SC routes, is associated with decreased levels of serum/plasma potassium, as well as of calcium, magnesium, and phosphate.[8]

Research
In an experiment investigating nontherapeutic metabolic and cardiovascular effects of therapeutic doses of beta-2-adrenoceptor agonists, Phillips et al.[9] administered IV infusions of salbutamol (albuterol) and rimiterol to four healthy male subjects. In response to "equivalent molar amounts of salbutamol and rimiterol," they observed "dose-related decreases in plasma potassium, phosphate and corticosteroids" as well as

"significant" hypocalcemia, hypomagnesemia, hyperlactatemia, and ketonemia and dose-related increases in plasma glucose, renin activity, serum insulin, and heart rate. They noted that with either drug, "special care is required for patients who may have abnormal glucose tolerance, potassium depletion, or be predisposed to lactic acidosis," and suggested that rimiterol "may be preferable for infusion because of its short plasma half-life."[9] Spector[8] reported that "beta adrenergic agonists can lower serum potassium levels predominantly when they are administered by the parenteral route." In particular he noted that dose-related hypokalemia has been demonstrated with albuterol given by the IM, IV, and SC routes, as well as with SC epinephrine. He further cautioned that comedication with agents such as corticosteroids, theophylline, diuretics, and digoxin could exacerbate potassium status and recommended further research into the "hypokalemic effect of all forms of beta agonists in view of their possible contribution toward arrhythmias and asthma deaths."[8] Subsequently, in a study of the effects of oral albuterol on serum and skeletal levels of digoxin in four healthy subjects, Edner and Jogestrand[10] observed a parallel reduction in the serum potassium concentration (0.58 mmol/L) and serum digoxin concentration, compared with control measurements.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The possibility of adverse effects on potassium status from albuterol, rimiterol, or related beta-2-adrenergic bronchodilators has been consistently demonstrated, but evidence is lacking as to the frequency of this effect or the efficacy of interventions to prevent or diminish it. The observed adverse effects on potassium levels are less likely to occur with use of albuterol via oral inhalation, the most common form of administration, particularly with occasional application in acute episodes. Clinical trials are warranted to determine the clinical significance of these effects of albuterol on potassium status and whether supportive coadministration of potassium and other minerals is safe and efficacious, as well as the comparative effects of food versus supplemental/prescribed sources. Pending substantive research findings, physicians prescribing albuterol, particularly those administering it parenterally, are advised to monitor potassium levels and consider potassium coadministration if indicated by direct findings or other factors associated with increased risk.

Amiloride

Amiloride (Midamor)
Combination drug: Amiloride and hydrochlorothiazide (Moduretic).

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Amiloride hydrochloride is an antikaliuretic-diuretic agent, which as a pyrazine-carbonyl-guanidine is unrelated chemically to other diuretics, including potassium-sparing agents. Because of its intended action of reducing urinary excretion of potassium, amiloride can produce a state of inappropriately elevated potassium levels, especially with concomitant angiotensin-converting enzyme (ACE) inhibitor therapy.[11,12] Further, exogenous sources of potassium, including potassium-rich foods such as fruit or food seasoning containing potassium chloride, can contribute to potassium accumulation in the presence of amiloride. Except for hyperkalemia (serum potassium levels >5.5 mEq/L), amiloride is generally thought to be well tolerated, and reports of significant adverse effects are infrequent.

Research and Reports

Published research is lacking, and case reports of hyperkalemia are generally uncirculated because this interaction is considered axiomatic, and coadministration is always accompanied by cautions of inherent risk.

Note: As a result of its potassium-sparing activity, amiloride is often prescribed in conjunction with medications, such as thiazides and amphotericin B, that cause electrolyte disturbances, especially potassium wasting, to mitigate these potentially dangerous adverse effects. These patterns of compensatory coadministration are discussed in the context of the respective medication(s) involved.

Clinical Implications and Adaptations

Amiloride is often prescribed because of demonstrated hypokalemia, but the risk of hyperkalemia warrants frequent monitoring when an ACE inhibitor and amiloride are administered concomitantly. Patient education is critical because potassium-rich foods are generally considered desirable for individuals wanting to enhance their cardiovascular health, and salt substitutes may be misconstrued as appropriate. Thus, despite good intentions, consuming even several pieces of fruit per day can be problematic for some individuals in the context of potassium-sparing agents such as amiloride. Regular monitoring and highly specific and practical dietary counseling are essential, with patients having even mildly compromised renal function at greatest risk.

Aminoglycoside Antibiotics, Including Gentamicin, Neomycin, and Tobramycin

Amikacin (Amikin), gentamicin (G-mycin, Garamycin, Jenamicin), kanamycin (Kantrex), neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin), netilmicin (Netromycin), paromomycin (monomycin; Humatin), streptomycin, tobramycin (AKTob, Nebcin, TOBI, TOBI Solution, TobraDex, Tobrex).

● **Consensus**

Effect and Mechanism of Action

Hypokalemia, as well as hypocalcemia, hypomagnesemia, and alkalosis, is a predictable outcome of renal tubular damage from aminoglycosides. Moreover, gentamicin-induced renal failure is potentiated by potassium depletion. Potassium administration may reduce the sequelae of aminoglycoside-induced hypokalemia but introduces significant risks in at-risk patient populations.

Research and Reports

Renal tubular damage is a well-established toxic effect of aminoglycosides, such as gentamicin, which has been demonstrated in animal studies and described in case reports. Clinically significant depletion of potassium (and magnesium) or other metabolic disturbances are assumed to be uncommon complications but are more likely to occur in elderly patients administered large doses over extended periods.[13-17] Findings from clinical trials specifically investigating coadministration of potassium, alone or with synergistic nutrients, in the prevention or treatment of aminoglycoside toxicity are lacking in the published literature.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing aminoglycosides on a chronic or repeated basis are advised to monitor closely for depletion of potassium and magnesium and other metabolic disturbances resulting from renal tubular damage and to consider prophylactic or compensatory nutritional support for such individuals. Serum creatinine, blood urea nitrogen (BUN), and creatinine clearance should be measured before initiating therapy and should be monitored throughout treatment, along with serum potassium and magnesium levels. Only after such assessment should increased intake of potassium (from dietary or supplemental sources) be undertaken, and then only under close supervision.

Enhancing potassium levels in response to potential compromise by aminoglycosides may be necessary and appropriate but needs to be approached with caution and care. Potassium levels can most easily be increased through consumption of several pieces of fruit each day. Slow-K, Micro-K, and K-dur are typical examples of the potassium preparations prescribed by physicians. However, increasing potassium intake by any means is usually contraindicated and often dangerous in patients with reduced kidney function, especially those on dialysis. Magnesium may also be appropriate for its general role in cardiovascular health; its tendency to be depleted by aminoglycosides, other drugs, and their adverse effects; and its role in maintaining intracellular potassium. Similar precautions regarding renal function apply to magnesium as well as potassium.

Amphotericin B (AMB; Fungizone)

Amphotericin B (AMB; Fungizone)

Similar properties but evidence indicating no or reduced interaction effects: Liposomal amphotericin, injection (AmBisome, Fungisome).

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
2. Probable

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Amphotericin B is a macrocyclic antifungal agent, similar in structure to nystatin, administered both systemically and topically for fungal infections. Amphotericin B is well known for inducing electrolyte disturbances. In particular, hypokalemia and potassium depletion (as well as magnesium wasting) are frequent complications of amphotericin B therapy, especially when combined with oral corticosteroids.[18,19] Moreover, potassium depletion appears to potentiate amphotericin B–induced toxicity to renal tubules.[20]

Hyperkalemia from rapid infusion or high doses in renally compromised patients is also possible, with attendant risks and adverse effects.

Research

Early research demonstrated reversible concentration-dependent loss of intracellular potassium in vitro and hyperkalemic ventricular arrhythmias in dogs.[21-26] Craven and Gremillion[27] reported two episodes of ventricular fibrillation with progressive hyperkalemia (up to 8-8.4 mEq/L) in an anuric patient during rapid infusion of high-dose amphotericin B (1.4 mg/kg over 45 minutes). They subsequently conducted animal experiments investigating risk factors of ventricular fibrillation during rapid amphotericin B infusion. First, they noted that prolonged infusion (≥3 hours) and concurrent hemodialysis "each prevented the development of hyperkalemia and ventricular arrhythmia." Thus, in trials involving two anuric patients receiving 4-hour infusions of amphotericin B during dialysis (0.7 and 1.0 mg/kg), they observed that peak amphotericin B concentrations in serum were lower and that serum potassium levels were maintained in the normal range. Likewise, in eight patients with normal renal function who received lower doses (0.7 ± 0.2 mg/kg) over 45 minutes, peak concentrations of amphotericin B in serum were also lower, with only slight increases in the serum potassium level. The authors thus recommended that "rapid infusion of amphotericin B not be used in patients with impaired potassium excretion unless accompanied by hemodialysis and careful potassium monitoring."[27]

Findings from a rodent study conducted by Bernardo et al.[20] suggest that "potassium depletion does not influence the acute renovascular effects of amphotericin B but potentiates its [renal] tubular toxicity."

Although substantive evidence is minimal, in some cases amiloride is combined with amphotericin B to prevent or mitigate the adverse effects of amphotericin B–induced hypokalemia and hypomagnesemia, especially in patients at high risk for complications resulting from these electrolyte disorders.[28] Other potassium-sparing agents might provide similar activity, but research is lacking.

Limited clinical research indicates the importance of regulating potassium, preventively or in response to observed hypokalemia, using amiloride and potassium coadministration. In a randomized clinical trial involving 20 neutropenic patients with various hematological disorders, Smith et al.[29] compared the prophylactic use of oral amiloride, 5 mg twice daily, concomitantly with IV amphotericin B (vs. amphotericin B alone) and demonstrated a decrease in potassium wasting. "Patients receiving amiloride had a significantly higher plasma potassium ($p < .01$), a significantly lower urinary potassium loss ($p < .01$), and required significantly less potassium chloride supplementation to maintain their plasma potassium within the normal range."[29] Subsequently, Bearden and Muncey[30] investigated the effect of amiloride (5-10 mg twice daily for 14.7 ± 12.6 days) in 19 oncology patients exhibiting marked electrolyte wasting from amphotericin B at 0.67 ± 0.30 mg/kg for a mean of 21.9 days (range, 7-57 days). They found that mean serum potassium concentrations increased in the 5 days before and after administration and reported a trend toward decreased potassium supplementation. Notably, these researchers adopted a more conservative approach than that of Smith et al.,[29] in that "amiloride was added to amphotericin B treatment only when patients began to exhibit excessive potassium requirements." Nevertheless, they concluded: "Early utilization of amiloride may be considered in patients with underlying risk factors for

hypokalaemia (i.e., leukaemia, cisplatin use, diuretics) in whom a prolonged course of amphotericin is anticipated . . . . This retrospective study suggests that amiloride may benefit patients by decreasing total potassium requirements and supplementation, as well as increasing serum potassium concentrations." They also cautioned that the "addition of another medication to a patient population receiving multidrug therapy is not recommended in all instances, and should be considered on a case-by-case basis."[30]

Pasic et al.[31] studied the safety and efficacy of liposomal amphotericin B (mean daily dose, 5 mg/kg; 2-6 mg/kg) in 15 pediatric patients receiving bone marrow transplants for primary immunodeficiency (PID). Of these, four developed mild hypokalemia, which resolved with increased potassium administration.

Reports

Hypokalemia is a frequently reported adverse effect of amphotericin B therapy, but hypokalemia-associated rhabdomyolysis tends to be a rare occurrence. Da Silva et al.[32] reported on a 10-year-old boy with hypokalemic rhabdomyolysis in the lower extremities after 1 week of amphotericin B therapy. Initial laboratory tests revealed a "serum potassium of 1.7 mEq/L and a serum creatinine phosphokinase of 3937 U/L plus myoglobulinuria." The patient "progressed to achieve full regression of muscular weakness after one week" after fluid expansion and IV potassium replacement.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians administering amphotericin B, whether in standard or liposomal form, are advised to be watchful for electrolyte disturbances, particularly depletion of potassium and magnesium. Such events are common and can be predicted in many patients, especially with extended or repeated amphotericin therapy. Amphotericin is almost always administered in inpatient hospital settings. Careful and frequent monitoring of serum electrolytes is required in all patients. Coadministration of potassium and possibly magnesium as a preventive, or at least reactive, measure is fundamental to comprehensive and judicious care, particularly in patients at high risk for potassium depletion. Amiloride is sometimes coadministered during amphotericin B therapy to decrease potassium wasting and can be considered a therapeutic option. It is noteworthy that amphotericin-induced potassium depletion can cause serious complications through its secondary effects on other medication, such as a potential increase in digitalis toxicity.

Angiotensin-Converting Enzyme (ACE) Inhibitors

Benazepril (Lotensin); combination drug: benazepril and amlodipine (Lotrel); captopril (Capoten); combination drug: captopril and hydrochlorothiazide (Accezide, Capto-Co, Captozide, Co-Zidocapt); cilazapril (Inhibace), enalapril (Vasotec); enalapril combination drugs: enalapril and felodipine (Lexxel); enalapril and hydrochlorothiazide (Vaseretic); fosinopril (Monopril), lisinopril (Prinivil, Zestril); combination drug: lisinopril and hydrochlorothiazide (Prinzide, Zestoretic); moexipril (Univasc), perindopril (Aceon), quinapril (Accupril), ramipril (Altace), trandolapril (Mavik).

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

Probability:
2. Probable

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

The ACE inhibitors can increase serum levels of potassium in certain individuals, particularly those with diabetes or compromised renal function.[33-35] The increased levels of intracellular potassium and magnesium associated with ACE inhibitor therapy may be an important mechanism by which ACE inhibitors reduce arrhythmias.[36-38] Some ACE inhibitors, such as enalapril, can significantly inhibit plasma aldosterone concentration and urinary excretion of aldosterone.[39] In general, these effects appear to be similar for long-acting ACE inhibitors such as enalapril and short-acting ACE inhibitors such as captopril.

The concomitant use of potassium with an ACE inhibitor drug increases the risk of hyperkalemia, especially with rapid introduction.[12] Potassium levels may become further elevated with simultaneous use of potassium-sparing diuretics, potassium-based salt substitutes, very-low-calorie diets, and NSAIDs (which reduce renal excretion of ACE inhibitors).[40-42] All these risks are amplified in the context of renal insufficiency.

Research

The concomitant use of ACE inhibitor and potassium-sparing diuretic therapy is a contraindication rather than a potassium interaction; in such cases, both potassium and potassium-sparing medications should be avoided. For example, Burnakis and Mioduch[43] noted the significant risk of hyperkalemia in patients receiving combined therapy with captopril and potassium. Chiu et al.[12] conducted a retrospective chart review of five patients, all with diabetes and older than 50, who were seen for hyperkalemia in emergency care after having amiloride HCl/hydrochlorothiazide added to an ACE inhibitor drug regimen 8 to 18 days before presenting. They stated that these findings "highlight the dangers of a precipitous rise in serum potassium levels in patients at risk for renal insufficiency, already receiving an angiotensin-converting enzyme (ACE) inhibitor, who are given a potassium-sparing diuretic."

Ohya et al.[39] administered enalapril (5 mg once daily) and captopril (12.5 mg three times daily) to 11 patients with mild essential hypertension and normal renal function for 1 week each in a crossover design, to compare effects of long-acting (enalapril) and short-acting (captopril) ACE inhibitors on serum electrolytes and circadian rhythm of urinary electrolyte excretion in relation to aldosterone status. Both agents "significantly decreased urinary K excretion" while "not significantly alter[ing] serum K level." Notably, the amplitude of urinary K excretion was decreased by both drugs, although the circadian rhythm (acrophase) was not affected by either drug. Both enalapril and captopril "significantly reduced blood pressure" (to a similar degree) while enalapril, but not captopril, "significantly inhibited plasma aldosterone concentration and urinary aldosterone excretion." Thus, although the primary finding of this trial was that "enalapril caused more sustained inhibition of aldosterone secretion" than captopril, they also noted that "both drugs showed similar effects on the K homeostasis in patients with mild essential hypertension."[39]

Nevertheless, the effects of ACE inhibitor therapy on potassium and magnesium may play an important role in their therapeutic effect. O'Keeffe et al.[36] investigated the effect of captopril

therapy on lymphocyte potassium and magnesium concentrations in patients with congestive heart failure (CHF). They compared lymphocyte potassium and magnesium in 18 patients taking furosemide and potassium for CHF before and 3 months after the introduction of captopril to 32 healthy controls. Nine of the treatment subjects exhibited decreased baseline lymphocyte magnesium and potassium concentrations, despite similar plasma electrolyte levels. Notably, there was a "significant increase in both lymphocyte potassium and magnesium levels" after 3 months' treatment with captopril and furosemide in these patients. Furthermore, nine patients "who had been taking a potassium-sparing combination diuretic also had an increase in lymphocyte magnesium" after the introduction of captopril. These authors concluded that "increased intracellular potassium and magnesium may be one mechanism whereby [ACE] inhibitors reduced arrhythmias and improve survival" in CHF patients.[36] In contrast, however, some of these same researchers subsequently examined the effect of 6 months' captopril (or nifedipine) therapy on lymphocyte magnesium and potassium levels in 28 patients treated for hypertension. They observed "no difference in serum or lymphocyte concentrations in the two groups compared to 45 healthy, normotensive controls."[37]

Overall, as summarized by Shionoiri[41] in a review of pharmacokinetic drug interactions involving ACE inhibitors (1993): "When ACE inhibitors are given, hyperkalaemia may occur in patients with renal insufficiency, those taking potassium supplements or potassium-sparing diuretics, and in diabetic patients with mild renal impairment."

Reports

Numerous case reports have been published describing hyperkalemia in patients undergoing ACE inhibitor therapy.[35,44-46] Stoltz and Andrews[40] described severe hyperkalemia during very-low-calorie diets and ACE inhibitor use. Ray et al.[42] reported two cases of severe hyperkalemia resulting from the concomitant use of salt substitutes (KCl) in hypertensive patients taking ACE inhibitors, in what they warned was "a potentially life threatening interaction." Serum potassium stabilized in the normal range after cessation of the salt substitute in each case. The authors concluded that "without vigilance the contribution of the salt substitute to hyperkalaemia would have been overlooked and an ACE inhibitor erroneously withdrawn."[42]

Clinical Implications and Adaptations

Health care professionals treating patients taking an ACE inhibitor are strongly encouraged to counsel these individuals to avoid unsupervised increases in potassium intake, in the form of supplements but also as high-potassium foods (e.g., fruit) or salt substitutes, on the basis of the increased risk for problematic reactions. A clinically significant increase in blood potassium levels represents an uncommon yet potentially serious adverse effect associated with ACE inhibitors. The importance of frank inquiry and detailed inventory of concomitant (or even occasional) medications, diet, nutrients and herbs cannot be overemphasized. Close supervision and regular monitoring are essential, particularly in individuals with compromised renal function. The prescription of potassium chloride or potassium-sparing medications is generally contraindicated during ACE inhibitor therapy.

Beta-Adrenoceptor Antagonists (Beta-Adrenergic Blocking Agents)

Evidence: **Nonselective agents (oral systemic forms):** Alprenolol, carteolol (Cartrol), levobunolol (AKBeta, Betagan), mepindolol, metipranolol (OptiPranolol), nadolol (Corgard), oxprenolol (Trasicor), penbutolol (Levatol), pindolol (Visken), propranolol (Betachron, Inderal LA, Innopran XL, Inderal); combination drug: propranolol and bendrofluazide (Inderex); sotalol (Betapace, Betapace AF, Sorine); timolol (Blocadren).

Similar properties but evidence indicating no or reduced interaction effects:

Beta-1-selective agents: Acebutolol (Sectral), atenolol (Tenormin); combination drugs: atenolol and chlortalidone (Co-Tendione, Tenoretic); atenolol and nifedipine (Beta-Adalat, Tenif); betaxolol (Kerlone), bisoprolol (Zebeta); combination drug: bisoprolol and hydrochlorothiazide (Ziac); esmolol (Brevibloc), metoprolol (Lopressor), nebivolol (Nebilet).

Mixed alpha-1/beta-adrenergic antagonists: Carvedilol (Coreg), celiprolol, labetalol (Normodyne, Trandate).

Beta-2-selective agents: Butoxamine (weak alpha-adrenergic agonist activity).

Related but evidence against extrapolation: Beta-adrenergic blocking ophthalmic drops: Betaxolol (Betoptic), carteolol (Cartrol, Ocupress), levobunolol (AKBeta, Betagan), metipranolol (OptiPranolol), timolol (Timoptic).

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Nonselective beta blockers inhibit both beta-1-adrenergic and beta-2-adrenergic receptors. Carvedilol, celiprolol, and labetalol exhibit mixed antagonism of both beta-adrenergic and alpha-1-adrenergic receptors.

In general, beta-adrenergic blockers can cause moderate increase in serum potassium concentrations and may lead to hyperkalemia. Beta-adrenergic blockade can enhance the rise and prolong the elevation in serum potassium without decreasing urinary potassium excretion.[47] "Beta-adrenergic mechanisms seem to be concerned in the extrarenal handling of the potassium-load," and beta blockade in humans can particularly impair extrarenal disposal of an acute potassium load.[47,48] This increase "cannot be explained by the retention of potassium in the organism, and is probably caused by the redistribution of potassium from intracellular to extracellular compartments." Further, the action inhibited by beta-blockade appears to function "presumably by inducing an increased uptake of potassium in muscular cells and liver cells" through beta-adrenergic mechanisms that are "probably of the beta 2-type."

Research

In contrast to beta-adrenergic agonists, which are often used to treat acute hyperkalemia, beta blockers can cause profound elevations of serum potassium. In an experiment involving nine healthy subjects, Rosa et al.[47] investigated the role of catecholamines in the regulation of potassium homeostasis by administering IV potassium chloride (0.5 mEq/kg) in the presence and absence of propranolol. The initial potassium infusion elevated serum potassium by 0.6 ± 0.09 mEq/L, and the addition of propranolol "augmented

the rise (0.9 ± 0.05 mEq per liter) and prolonged the elevation in serum potassium without decreasing urinary potassium excretion." The authors concluded that "Beta-adrenergic blockade impairs ... extrarenal disposal of potassium load" and that such findings "suggest that in patients with impaired potassium disposal, the risk of hyperkalemia may be increased when sympathetic blockade is induced."[47]

In a review (1983) of the effect of adrenergic blockade on potassium concentrations in different conditions, Lundborg[48] cautioned that in theory "there are several conditions in which it is important to have a defence against hyperkalaemia from exogenous or endogenous sources, for example, during heavy physical exercise, after a potassium-rich meal, or after traumatic tissue damage." He concluded: "Available data indicate that non-selective beta-blockade increases serum potassium concentrations during and after heavy exercise and during coronary bypass."

Reports

Arthur and Greenberg[49] described the cases of three renal transplant recipients who "developed potentially life-threatening hyperkalemia" after IV administration of labetalol for postoperative hypertension.

Clinical Implications and Adaptations

Physicians prescribing beta-adrenergic blockers are advised to caution patients to avoid potassium in supplements, medications, and salt substitutes. Moreover, eating large servings of fruit rich in potassium, such as bananas, is generally contraindicated without prior discussion and ongoing monitoring. Nevertheless, enhanced potassium intake may be appropriate in certain patients comedicated with potassium-depleting diuretics or after an episode of vomiting or diarrhea. Close supervision and regular monitoring of potassium levels and other relevant clinical parameters are essential, especially with changes in medication regimens, diet, and intake of natural agents such as herbs or nutrients. Again, as noted by Lundborg,[48] the risk of hyperkalemia is increased after heavy physical exercise, a potassium-rich meal, or traumatic tissue damage, all of which may cause a rapid elevation in circulating potassium levels, which can be exacerbated in patients taking beta-blocker medications.

Carbenoxolone (CBX)

See Licorice in Herb-Nutrient Interactions.

Carbonic Anhydrase Inhibitors, Potassium Depleting

Evidence: Acetazolamide (Diamox), diclofenamide (dichlorphenamide; Daranide), dorzolamide (Trusopt); combination drug: dorzolamide and timolol (Cosopt); furosemide (BAN, frusemide, INN; Lasix), methazolamide (Glauctabs, Neptazane).
Similar properties but evidence lacking for extrapolation: Brinzolamide (Azopt), topiramate (Topamax), zonisamide (Zonegran).
See also Diuretics, Potassium Depleting.

Interaction Type and Significance
≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **4. Plausible**
Evidence Base: ▽ **Mixed**

Effect and Mechanism of Action

The enzyme carbonic anhydrase catalyzes the reversible reaction involving the hydration of carbon dioxide and the dehydration of carbonic acid with attendant potassium loss. Agents with diverse mechanisms act as carbonic anhydrase inhibitors in the treatment of a variety of conditions, most of which involve fluid regulation, including those involving intraocular pressure. For example, acetazolamide achieves alkalinization of the urine and promotion of diuresis through its action on this reversible hydration-dehydration reaction in the kidneys and resultant renal loss of bicarbonate (HCO_3^-), along with sodium, water, and potassium. In high doses, all carbonic anhydrase inhibitors cause some decrease in renal blood flow and glomerular filtration rate. In general, with the exception of specific agents such as furosemide (which is also a loop diuretic) and acetazolamide, methazolamide and most other drugs in this class tend to have a weak and transient diuretic effect and are not used as systemic diuretics.

Research

Clinical trials investigating the systemic effect of carbonic anhydrase inhibitors on potassium status are lacking. Although acetazolamide is used for its diuretic action in the treatment and prevention of high-altitude pulmonary edema, and furosemide is well known as a loop diuretic, most agents in this class are used in the treatment of ocular conditions such as glaucoma. Consequently, the limited available data indicate that in most cases the degree of potassium loss is unlikely to be of clinical significance, even with chronic administration, barring other dominant influences or confounding factors.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing carbonic anhydrase inhibitors, with the significant exceptions of furosemide and acetazolamide for systemic cardiovascular conditions, can generally assume that adverse effects on potassium status are improbable in most patients not taking other potassium-depleting medications or otherwise compromised. As a cautionary suggestion, and for the benefit of overall nutritional status, health care professionals can reiterate support for the healthful practice of regularly consuming plentiful fresh fruits and vegetables and decreasing intake of salt (specifically sodium) and processed foods. Monitoring is important because excessive alkalinization of the urine and metabolic acidosis (resulting from decreases in plasma bicarbonate) may lead to a disequilibrium in carbon dioxide transport in the erythrocytes.

Cisplatin

Evidence: Cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ).
Similar properties but evidence indicating no or reduced interaction effects: Carboplatin (Paraplatin), oxaliplatin (Eloxatin).

Interaction Type and Significance
≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**
⊕✗ **Bimodal or Variable Interaction, with Professional Management**
✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

Probability: **1. Certain**
Evidence Base: ◉ **Emerging to** ● **Consensus**

Effect and Mechanism of Action

Cisplatin can induce renal functional damage and cause chronic tubulopathy, characterized by magnesium and potassium wasting, reduced calcium excretion, metabolic alkalosis, and a strong tendency to hypomagnesemia and hypokalemia. In this common complication an unrecognized and untreated magnesium depletion can lead to a potassium depletion that is refractory to repletion with potassium alone.[50] The resulting hypokalemia can be corrected only with concomitant administration of magnesium with potassium.[51] Thus, this interaction demonstrates the critical role that magnesium plays in maintaining intracellular potassium.

Cisplatin and related chemotherapeutic agents cause renal toxicity to varying degrees. Coadministration of potassium, magnesium, or other nutrients adversely affected by these drugs is constrained by compromised urinary excretion and may be contraindicated in some patients with borderline renal function.

Research

Limited but consistent research findings parallel and confirm clinically based consensus regarding the effects of cisplatin in depleting potassium. Buckley et al.[52] documented hypomagnesemia in 66 patients receiving a five-drug combination chemotherapy regimen containing low-dose cisplatin. They observed that 38 (76%) of 50 patients receiving treatment every 4 weeks became hypomagnesemic during treatment, and that the incidence increased with the cumulative cisplatin dose, ranging from 41% after a single course to all patients receiving six cycles of therapy. Notably, patients receiving the combination at a longer interval (8 vs. 4 weeks) between cycles exhibited a lower incidence. The authors thus reported that the incidence and severity of hypomagnesemia was dose dependent. They also noted that the higher incidence of hypomagnesemia observed in this study might be related to an interaction of cisplatin with one or more of the drugs in the combined regimen.[52] Bianchetti et al.[53] studied renotubular handling of potassium, sodium, calcium, phosphate, hydrogen ions and glucose, and urinary concentrating ability in three children (age 8-11 years) with renal magnesium loss, persisting for longer than 2 years after discontinuation of cisplatin treatment for neuroblastoma, and compared these findings with group of healthy children serving as controls. Apart from renal magnesium wasting, there was a clear tendency toward reduced calciuria associated with normal or slightly elevated plasma calcium, and plasma potassium levels "tended to be low" (3.4-3.7 mmol/L). Plasma chloride was normal, and plasma "creatinine levels, glucosuria and phosphaturia, and urinary concentrating capacity were adequate." They noted that overall patterns in these children were similar to those observed in three children (age 4½-13 years) with primary renotubular hypomagnesemia-hypokalemia and hypocalciuria. Thus, the authors concluded that "cisplatin may induce renal functional damage identical to that found in primary renotubular hypomagnesaemia-hypokalaemia with hypocalciuria."[53]

Reports

Rodriguez et al.[50] described "two patients with hypomagnesemia-associated refractory hypokalemia following cisplatin therapy." They found that potassium administration failed to correct the potassium deficit and "profound hypokalemia persisted until hypomagnesemia was recognized and corrected" after the eleventh and ninth days, respectively. Based on these clinical experiences, the authors recommended that "both serum K ion and Mg levels should routinely be assessed in patients who require cisplatin therapy."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians administering cisplatin will want to monitor electrolyte status closely and will usually need to coadminister a wide range of nutrients, including potassium, to mitigate adverse effects and optimize therapeutic outcome. In clinical practice, adverse effects on potassium status are considered a certainty with cisplatin. Carboplatin has considerably less renal toxicity (but more marrow suppression), and oxaliplatin also has less renal toxicity but more neurotoxicity. Given the high probability of renal damage with these agents, regular monitoring of renal function is obligatory, and nutrient administration can proceed only within the constraints of such systemic limitations, particularly resultant compromise of urinary excretion of potassium and magnesium. Thus, many oncologists treating with standard-dose cisplatin routinely include potassium and magnesium in the pre/post–IV hydration fluid.

In a review of the relationship between magnesium deficiency and potassium depletion refractory to repletion, Whang et al.[51] concluded by recommending that "(1) serum Mg be routinely assessed in any patients in whom serum electrolytes are necessary for clinical management and (2) until serum Mg is routinely performed, consideration should be given to treating hypokalemic patients with both Mg as well as K to avoid the problem of refractory K repletion due to coexisting Mg deficiency."

Further research may be warranted to determine factors influencing degree of risk and adverse effects among patients treated with cisplatin and to develop clinical guidelines for integrative therapeutics incorporating nutritional support.

Colchicine

Colchicine

Interaction Type and Significance

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

Probability:
3. Possible or
2. Probable

Evidence Base:
● **Consensus**, though
○ **Preliminary**

Effect and Mechanism of Action

Colchicine can impair absorption of potassium (and other nutrients) and may increase potassium loss (as well as loss of other minerals, e.g., calcium and magnesium).[54,55] Depletion can be prevented or corrected with nutrient coadministration.

Research

For decades, colchicine has been widely viewed as likely to cause potassium loss.[54] However, clinical trials specifically investigating and confirming this adverse effect are lacking.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing colchicine, especially for an extended period and in patients at greater risk for overall compromised nutritional status, are advised to monitor for imbalances and depletions in potassium and other nutrients. Colchicine is a potent anti-inflammatory often used as therapy in acute attacks of gout, which carries significant toxicity. It is sometimes used on a more chronic basis for rare disorders such as familial Mediterranean fever. Conservative practice also suggests

consideration of preventive or corrective coadministration of potassium, as well as magnesium, calcium, and beta-carotene. Vitamin B_{12} may also be indicated if neuropathies develop. Dietary changes, especially restricting purine intake and reducing alcohol consumption, as well as adding cherry juice, can also be therapeutic in the treatment of individuals with gout.

Corticosteroids, Oral

Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol) prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).

Similar properties but evidence indicating no or reduced interaction effects: Inhaled or topical corticosteroids.

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **3. Possible**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Oral corticosteroids increase urinary excretion of potassium and can cause hypolkalemia.[56-58] The mineralocorticoid action of cortisol causes a decrease in serum potassium concentration, together with stimulation of intestinal sodium absorption and an increase in serum sodium concentration, the combination of which can lead to water retention, weight gain, and increased risk of hypertension. Although used for its mineralocorticoid effects, fludrocortisone is classified as a glucocorticoid and an aldosterone agonist with physiological effects similar to but more potent than hydrocortisone. In general, these adverse effects vary with agent, dosage, duration, and comedications.

Potassium depletion may contribute to the mineralocorticoid-induced sodium retention. Conversely, potassium administration can augment urinary sodium excretion, attenuate mineralocorticoid-induced sodium retention, and reverse hyperaldosteronism.[59-63]

Research

The effects of oral corticosteroids on urinary excretion of potassium is well established, but consensus is lacking (and specific research absent) regarding the clinical significance of this influence.[57] Nevertheless, there is risk of hypokalemia during prolonged, high-dose corticosteroid therapy.[56,64]

The role of external potassium balance in modulating mineralocorticoid-induced sodium retention in humans remains uncertain. However, in a small trial involving eight healthy subjects treated with fludrocortisone, Krishna and Kapoor[61] demonstrated that potassium administration can ameliorate mineralocorticoid-induced sodium retention and enhance urinary sodium excretion. Conversely, fludrocortisone is used to treat interdialytic hyperkalemia in dialysis patients or may be useful, in combination with spironolactone, to correct sodium and potassium losses in secretory diarrhea.[65,66]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing oral corticosteroids, especially for an extended period and in patients at greater risk for overall compromised nutritional status, are advised to monitor for imbalances and depletions in potassium and other nutrients. The minimal available evidence suggests that clinically significant potassium depletion is possible in some patients depending on the patient's general health, including diet, exercise, and other key physiological influences, and the potency of the particular agent(s) applied. In patients whose potassium status may be at risk, the consumption of fruit, vegetables, and other foods rich in potassium is usually the simplest and most effective means of preventing or correcting potential potassium depletion associated with long-term steroid therapy.

Cotrimoxazole (Sulfamethoxazole and Trimethoprim)

Cyclosporine

Cyclosporine (Ciclosporin, cyclosporin A, CsA; Neoral, Sandimmune, SangCya).

Interaction Type and Significance

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

Probability: **3. Possible**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Cyclosporine, an inhibitor of calcineurin, can induce hyperkalemia through different mechanisms, most notably immunosuppressant-induced nephrotoxicity, and chronic progressive tubulointerstitial fibrosis/arteriopathy in particular.[67] "Cyclosporin A (CsA)–induced hyperkalemia is caused by alterations in transepithelial K^+ secretion resulting from the inhibition of renal tubular Na^+,K^+-ATPase activity."[68] An obvious cause, found in many cases, derives from CsA-induced nephrotoxicity, a well-known adverse effect, that "causes a reduction in glomerular filtration rate through vasoconstriction of the afferent glomerular arterioles and may result in acute renal failure."[69] "Calcineurin inhibitor-induced acute renal failure may occur as early as a few weeks or months after initiation of cyclosporin therapy."[67] Nevertheless, other individuals exhibiting adequate kidney function have developed hyperkalemia, possibly because of tubular resistance to aldosterone.[69] Overall, dose-related renal tubule dysfunction, tubulointerstitial fibrosis/arteriopathy, and secondary hypoaldosteronism are considered the primary reasons for CsA-associated hyperkalemia, but no conclusive evidence has emerged to provide a comprehensive explanation for this phenomenon.

Reports and Research

Cyclosporin A and other immunosuppressive drugs are generally known to "induce either hypoaldosteronism or pseudo-hypoaldosteronism presenting with hyperkalemia and metabolic acidosis" after renal transplantation.[70]

Caliskan et al.[69] reported four cases of cyclosporine-associated hyperkalemia in allogeneic blood stem cell transplant patients "despite adequate kidney function." The authors proposed that hyperkalemia was caused by renal tubule dysfunction and secondary hypoaldosteronism. Takami et al.[71] reported the cases of two patients with advanced renal cell carcinoma who developed hyperkalemia during CsA therapy after allogeneic hematopoietic stem cell transplantation. They noted that this adverse effect occurred despite adequate renal function; both patients developed hyperkalemia, and

cyclosporine, "the only pharmaceutical agent to which this electrolyte abnormality could be attributed," contributed to "tubular resistance to aldosterone." They also suggested that "the presence of a single functional kidney may be a risk factor for isolated hyperkalemia" resulting from cyclosporine.

In a 1995 study involving 24 renal transplant recipients 6 months after transplantation, Laine and Holmberg[72] investigated renal and adrenal mechanisms in cyclosporine-induced hyperkalemia observed in 11 of these patients. "The TTKGs [transtubular potassium concentration gradients] were low normal or reduced in both normo- and hyperkalaemic patients implying inhibition of K^+ secretion." The hyperkalemic patients received more CsA, and serum potassium concentration correlated with CsA dose. Notably, adrenal function exhibited "no clear effect," and the authors of this relatively early study concluded that hyperkalemia "was not fully explained by renal mechanisms."

In a 1999 prospective study of 49 kidney allograft recipients who received transplants before age 5 years, Qvist et al.[73] documented "excellent long-term graft survival and good graft function" 5 to 7 years after renal transplantation. Nevertheless, the authors noted that whereas "sodium handling remained intact, ... hyperuricemia was seen in 43-67%; 17-33% showed abnormal handling of potassium; and most patients had a subnormal concentrating capacity."

Higgins et al.[74] studied and compared the frequency and severity of nephrotoxicities, hyperkalemia, and hyponatremia in renal transplant recipients treated with cyclosporine versus tacrolimus. In this retrospective study they investigated sodium and potassium handling in 125 patients initially treated with cyclosporine ($n = 80$) or tacrolimus ($n = 45$) during the first 90 days after renal transplantation. They observed that serum potassium levels were higher in patients treated with tacrolimus than in those treated with cyclosporine, noting that hyponatremia was more likely in subjects with hyperkalemia.

Dangerous disturbances in potassium status and concentrations in patients being treated with cyclosporine have been reported repeatedly, and polypharmacy using several different agents has been used to reverse these adverse effects. Thyroxine is known to enhance renal cortical Na^+,K^+-ATPase activity. In a rodent experiment, You et al.[68] found that coadministration of thyroxine "prevented CsA-induced hyperkalemia and reduced creatinine clearance, Na^+,K^+-ATPase activity, and severity of the histologic changes in the renal tubular cells." Limited research indicates that ACE inhibitors or angiotensin II type I receptor antagonists such as losartan may be effective and well tolerated in the treatment of hypertension in renal transplant recipients at heightened risk of hyperkalemia and hyperuricemia from decreased renal blood flow and glomerular filtration rate associated with a single kidney and concomitant cyclosporine use.[75] One study noted that "in this high-risk population, the effects on serum potassium levels are less marked with losartan than with enalapril."[76] In a clinical trial involving 21 renal transplant patients under CsA therapy and 12 healthy controls, Heering et al.[70] investigated the relationship between renal allograft function under CsA therapy and plasma aldosterone concentration, potassium and water homeostasis, and mineralocorticoid receptor (MR) expression level in peripheral leukocytes. They concluded that "aldosterone resistance in kidney transplantation is in part induced by a down-regulation of mineralocorticoid receptor expression." They also noted that administration of fludrocortisone reversed hyperkalemia and metabolic acidosis without significant effect on MR expression. Similarly, Singer et al.[77] described the prompt reversal of hyperkalemia and other "severe life-threatening complications" through administration of glibenclamide in three critically ill patients who developed "potassium-channel syndrome" after receiving cyclosporine or other drugs with K(ATP) channel-opening properties. Thus, although several strategies have been evaluated to attenuate cyclosporine-induced nephropathy, evidence of their efficacy remains preliminary.

Clinical Implications and Adaptations

Physicians treating allograft patients with cyclosporine will generally be monitoring for renal damage and associated hyperkalemia and other disturbances in electrolyte balance. Concomitant potassium in such patients is generally contraindicated, and frank inquiry as to lifestyle practices, including a thorough inventory of dietary and supplement intake, is essential to comprehensive management of such patients.

Digoxin and Related Cardiac Glycosides

Digoxin (Digitek, Lanoxin, Lanoxicaps, purgoxin).
Extrapolated, based on similar properties: Deslanoside (cedilanin-D), digitoxin (Cystodigin), ouabain (g-strophanthin); foxglove plant *(Digitalis lanata)*.

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

Probability:
2. Probable

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

The central role of potassium in maintaining proper function of cardiac (and other) muscles is a basic physiological precept in clinical medicine. The safe use of digoxin requires stable blood potassium levels because hypokalemia may predispose to digitalis toxicity and dangerous cardiac arrhythmias. However, digoxin impairs potassium transport from the blood into cells.[78] Furthermore, potassium depletion, induced by concomitant diuretic use and often secondary to hypomagnesemia, is quite common among individuals treated with digoxin. Conversely, an overdose of digoxin can cause a potentially fatal hyperkalemia.

Reports and Research

As early as 1960, in a paper on the relationship between digitalis and potassium in the context of surgery, Lown et al.[78] discuss impaired potassium transport from the blood into cells caused by digoxin. In reporting on correlations with serum digoxin level in five cases of suicidal and accidental digoxin ingestion, Smith and Willerson[79] noted that potentially fatal hyperkalemia can result from an overdose of digoxin.

In 1985, Whang et al.[80] published their findings on the frequency of hypomagnesemia in hospitalized patients receiving digitalis. In measuring serum sodium, magnesium, and potassium levels in 136 serum samples sent to the laboratory for digoxin assay, they found that hyponatremia occurred most frequently (21%), followed by hypomagnesemia in 19%, hypokalemia in 9%, and hypermagnesemia in 7%. They noted that the "twofold frequency of hypomagnesemia" compared to hypokalemia "indicates that clinicians are more attuned to avoiding hypokalemia than hypomagnesemia in patients receiving digitalis," and added that their "observation suggests that

hypomagnesemia may be a more frequent contributor than hypokalemia to induction of toxic reactions to digitalis." Thus, they concluded that electrolyte monitoring, both of magnesium and potassium, is critical "in patients receiving digitalis, who often are also receiving potent diuretics."

Schmidt et al.[81] found that the impairment of extrarenal potassium homeostasis by heart failure and digoxin treatment may be counterbalanced by exercise. Based on the finding that "extrarenal potassium handling is altered as a result of digoxin treatment," the authors proposed that this is "likely to reflect a reduced capacity of skeletal muscle Na/K-ATPase for active potassium uptake because of inhibition by digoxin (similar to that seen with beta-blockers), adding to the reduction of skeletal muscle Na/K-ATPase concentration induced by heart failure *per se*." Consequently, however, "in heart failure patients, improved haemodynamics induced by digoxin may . . . increase the capacity for physical conditioning."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing digoxin or related cardiac glycosides need to monitor for potassium (and magnesium) depletion. Unsupervised use of potassium supplements (or even high intake of potassium-rich foods) is generally contraindicated during digitalis therapy. However, when coadministration of potassium may be indicated, particularly in the context of potassium-depleting diuretics, oral preparations may not be as effective or as well tolerated as consistent dietary consumption of fruit and other foods rich in potassium. Education and support for a regular program of moderate exercise can be therapeutically valuable in most patients and consistent with broader knowledge of cardiovascular health and risk factors. Close supervision and regular monitoring are inherently appropriate in all digitalized patients.

Diuretics, Potassium Depleting, Including Loop and Thiazide Diuretics

Loop diuretics: Bumetanide (Bumex), ethacrynic acid (Edecrin), furosemide (Lasix), torsemide (Demadex).
Thiazide diuretics: Bendroflumethiazide (bendrofluazide; Naturetin); combination drug: bendrofluazide and propranolol (Inderex); benzthiazide (Exna), chlorothiazide (Diuril), chlorthalidone (Hygroton), cyclopenthiazide (Navidrex); combination drug: cyclopenthiazide and oxprenolol hydrochloride (Trasidrex); hydrochlorothiazide (Aquazide, Esidrix, Ezide, Hydrocot, HydroDiuril, Microzide, Oretic); combination drugs: hydrochlorothiazide and amiloride (Moduretic); hydrochlorothiazide and captopril (Acezide, Capto-Co, Captozide, Co-Zidocapt); hydrochlorothiazide and enalapril (Vaseretic); hydrochlorothiazide and lisinopril (Prinzide, Zestoretic); hydrochlorothiazide and losartan (Hyzaar); hydrochlorothiazide and metoprolol (Lopressor HCT); hydrochlorothiazide and spironolactone (Aldactazide); hydrochlorothiazide and triamterene (Dyazide, Maxzide), hydroflumethiazide (Diucardin), methyclothiazide (Enduron), metolazone (Zaroxolyn, Mykrox), polythiazide (Renese), quinethazone (Hydromox), trichlormethiazide (Naqua).
Thiazide-like diuretics: Indapamide (Lozol).

Evidence Base:
● Consensus

Effect and Mechanism of Action

Thiazide, loop, and similar diuretics are often referred to as "potassium depleting" because by definition they increase potassium excretion with diuresis; in practice, they concurrently deplete magnesium at the cellular level.[82] The diuretic-induced magnesium deficiency can lead to refractory potassium depletion but may not be detectable through routine serum magnesium determinations.[51,83]

Research

Potassium wasting with these medications is axiomatic, and hypokalemia is a common finding in those taking diuretic medications, especially the elderly. Avoiding hypokalemia is generally agreed to be beneficial in several cardiovascular disease states, including acute myocardial infarction, heart failure, and hypertension. Nevertheless, data from direct research into diuretic-induced hypokalemia are limited. Moreover, clinically significant differences in the severity of effects on potassium status between high-dose and low-dose diuretics, as well as oral versus intravenous administration, have been proposed. Furthermore, the available research does provide some important insights that depart from common assumptions.

Not all patients receiving treatment with "potassium-depleting" diuretics necessarily develop clinically significant (or at least readily detectable) decreases in potassium concentrations. In three yearly multicenter surveys involving 18,872 patients with initially normal baseline serum potassium, Zuccala et al.[84] investigated older age and in-hospital development of hypokalemia in the 4035 patients who started receiving loop diuretics during their hospital stay. After adjusting for a number of variables, age and use of parenteral (but not oral) loop diuretics were associated with hypokalemia. The authors concluded that "older age is independently associated with the in-hospital development of hypokalemia, particularly among patients taking loop diuretics" and recommended monitoring of serum potassium levels "when older patients are treated with these agents."

Franse et al.[85] analyzed data of 4126 participants in a 5-year, randomized, placebo-controlled clinical trial of chlorthalidone-based treatment of isolated systolic hypertension in older persons to determine whether hypokalemia that occurs with low-dose diuretics is associated with a reduced benefit on cardiovascular events. They found that after "adjustment for known risk factors and study drug dose, the participants who received active treatment and who experienced hypokalemia had a similar risk of cardiovascular events, coronary events, and stroke as those randomized to placebo." However, "within the active treatment group, the risk of these events was 51%, 55%, and 72% lower, respectively, among those who had normal serum potassium levels compared with those who experienced hypokalemia." Thus, they concluded that subjects who had hypokalemia after 1 year of treatment with a low-dose diuretic "did not experience the reduction in cardiovascular events achieved among those who did not have hypokalemia." Besides demonstrating that treatment with a thiazide diuretic led to a reduction in serum potassium levels in some participants, these findings indicate that patients exhibiting decreased potassium levels were also more likely to experience cardiovascular events, such as heart attacks, heart failure, sudden cardiac death, stroke, and aneurysm.

The interrelationship between potassium (K) and magnesium (Mg) depletion patterns is an important topic with significant implications for normal electrolyte balance and cardiac function. In a 1992 paper, Whang et al.[51] reviewed experimental and clinical observations supporting the view that uncorrected Mg deficiency impairs repletion of cellular K. "[C]onsistent with the observed close association between K and Mg depletion," they found that concomitant "Mg deficiency in K-depleted patients ranges from 38% to 42%." Although this refractory "K repletion due to unrecognized concurrent Mg deficiency can be clinically perplexing," they note that it "may be operative in ... patients receiving potent loop diuretics" as well as other medications. Based on these findings, they recommend that "(1) serum Mg be routinely assessed in any patients in whom serum electrolytes are necessary for clinical management and (2) until serum Mg is routinely performed, consideration should be given to treating hypokalemic patients with both Mg as well as K to avoid the problem of refractory K repletion due to coexisting Mg deficiency."[51]

The complications arising from the effects of potassium depletion have broad implications for an at-risk cardiovascular patient population. For example, low preoperative serum potassium levels can adversely influence perioperative outcomes in cardiac surgery patients. Wahr et al.[2] conducted a prospective, observational, case-control study to determine the prevalence of abnormal preoperative serum potassium levels and whether such abnormal levels are associated with adverse perioperative events. Analyzing data gathered from 24 diverse U.S. medical centers in a 2-year period, they found that perioperative arrhythmias occurred in 1290 (53.7%) of 2402 patients and that "serum potassium level less than 3.5 mmol/L was a predictor" of serious perioperative arrhythmia, intraoperative arrhythmia, and postoperative atrial fibrillation/flutter, and "these relationships were unchanged after adjusting for confounders." These authors concluded: "Although interventional trials are required to determine whether preoperative intervention mitigates these adverse associations, preoperative repletion is low cost and low risk, and our data suggest that screening and repletion be considered in patients scheduled for cardiac surgery."[2]

Ruml et al.[86] conducted two clinical trials investigating the effect of varying doses of potassium-magnesium citrate on thiazide-induced hypokalemia and magnesium loss. In subjects first administered hydrochlorothiazide, 50 mg daily, these researchers found that three different "dosages of potassium-magnesium citrate significantly increased serum potassium concentration, with > 80% of subjects regaining normal values despite continued thiazide therapy." They concluded that potassium-magnesium citrate "not only corrects thiazide-induced hypokalemia, but also may avert magnesium loss while providing an alkali load." However, "higher dosages," such as 70 mEq potassium, 35 mEq magnesium, and 105 mEq citrate per day, are "probably required for the prevention of magnesium loss and adverse symptoms of thiazide therapy."[87]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

In practice, it is generally advisable to coadminister both potassium and magnesium when prescribing any potassium-depleting diuretic, except in cases involving those with renal insufficiency. For long-term care, coadministration of potassium in the dosage range of several hundred milligrams to several grams per day is usually appropriate, depending on the individual's diet, age, genetic predisposition, medications, and other factors. Potassium deficiency status can be evaluated by monitoring RBC potassium levels or, more conventionally, serum potassium concentration. Assessment of potassium status may be appropriate but is often not essential, because low serum potassium is not required for patients to benefit from potassium coadministration. However, since administration of potassium (and/or magnesium) can be risky, and is usually contraindicated, in patients with renal insufficiency, kidney function tests are critical before initiating, and periodically through the course of, concomitant repletion therapy.

Administration of potassium, magnesium, or other electrolyte needs to be maintained for 6 months to compensate for any drug-induced tissue depletion pattern and throughout the duration of, and possibly after conclusion of, relevant diuretic therapy. A typical complementary magnesium dose for most individuals would be in the range of 300 to 500 mg per day, preferably as magnesium citrate, malate, gluconate, or glycinate. A multimineral formulation would add support against parallel depletions of other vulnerable minerals. Beyond potassium and magnesium, clinical care within an integrative setting might also emphasize a diet rich in minerals, vitamins, antioxidants, and essential fatty acids as part of an evolving and individualized approach to cardiovascular therapeutics involving health care professionals trained and experienced in multiple therapeutic disciplines.

Ipecac

See Ipecac in Herb-Nutrient Interactions.

Laxatives and Stool Softeners

Fast-acting laxative agents: Glycerin-containing suppositories (Fleet), magnesium-containing products (Phillips' Milk of Magnesia Magnesium Citrate Solution); bisacodyl tablets (Dulcolax), monobasic sodium phosphate monohydrate and dibasic sodium phosphate heptahydrate (Fleet Phospho-soda Oral Saline Laxative), senna (*Cassia senna, Cassia argustifolia;* Black-Draught, Fletcher's Castoria, Gentlax, Senexon, Senna-Gen, Senekot, Senolax).

Enemas: Bisacodyl enemas (Dulcolax), monobasic sodium phosphate monohydrate and dibasic sodium phosphate heptahydrate (Fleet enema).

Slow-acting laxative agents: Bulk-forming laxatives: Methylcellulose (Citrucel), polycarbophil (FiberCon), psyllium (Metamucil, Konsyl-D).

Stool softeners: Docusate (Colace, Surfak), mineral oil (Agoral, Kondremul Plain, Milkinol, Neo-Cultol, Petrogalar Plain).

Prescription laxative agents: Lactulose (Chronulac), polyethylene glycol (Miralax), polyethylene glycol–electrolyte solution (CoLyte, GoLYTELY, NuLytely).

▽ **Mixed** and
○ **Preliminary**

Effect and Mechanism of Action

Excessive or repeated use of any laxative can deplete potassium (and a wide range of other nutrients) through a variety of

mechanisms, including impaired absorption and altered transit time. Short-term use of cathartic laxatives, as in the context of colon cleansing for radiological examinations, can cause acute drops in serum potassium that may be particularly dangerous in patients on diuretic or digitalis therapy and those with cardiac conditions or otherwise susceptible to arrhythmias.[88] Among its several actions, docusate administration stimulates net secretion of potassium.[89] Mineral oil, as a lipid solvent, may interfere with normal absorption of potassium and other nutrients and absorb many substances. Inherently, these factors are aggravated in the context of compromised nutritional intake and limited physical activity. Potassium coadministration, through dietary or supplemental prescription intake, can usually prevent or reverse any disturbances in potassium status.

Stimulant-type laxatives such as bisacodyl may both reduce potassium absorption and cause excessive potassium loss, as well as sodium depletion and hyperreninemia, most probably through two mechanisms: (1) loss of potassium as a result of stimulation of mucus secretion in intestinal mucosa and (2) a "dual effect of potassium on aldosterone secretion, with renin as a mediator."[90-93] Thus, hypokalemia can result from abuse or chronic bisacodyl use.

Reports and Research

Fleming et al.[92] reported the case of a patient "with marked chronic hypokalemia (potassium, 1.7 to 2;3 meq/litre) and sodium depletion secondary to laxative abuse and dietary inadequacy."

Moriarty et al.[89] used an intestinal perfusion technique to investigate the mechanism of action of docusate in the human jejunum and observed that it "stimulated net secretion of water, sodium, chloride and potassium and inhibited net absorption of glucose and bicarbonate."

In a prospective study involving 320 patients, Ritsema and Eilers[88] investigated the impact of colon cleansing before procedures on serum potassium concentrations and the efficacy of potassium administration in preventing serious hypokalaemia. Of the four subject subgroups, two were being treated with diuretics, and one of those also received potassium. "Hypokalaemia was present prior to cleansing in six (11%), and after cleansing in 20 (36%) of the 55 patients in the group 1 patients on diuretics but without potassium supplements. There was, after cleansing, no significant fall in serum potassium in the group 2 patients on diuretics who received potassium supplements." Notably, no hyperkalemia resulted from potassium coadministration. Likewise, both subgroups not receiving diuretics, one of which received a 2-day preparation of 15 g magnesium sulfate and 10 mg bisacodyl twice daily and the other a 1-day preparation of 2.4 mg sennoside, exhibited a "significant fall of the mean level of serum potassium." Thus, the authors concluded that "both 1 day and 2 days of cleansing with cathartics may result in a significant fall in serum potassium, which can be prevented by oral potassium supplements." In particular, they noted that administration of 15 mL of potassium chloride with 0.9 mmol K/mL three times daily during the preparation "in patients on diuretics may be prudent to avoid the risk of cardiac arrhythmia."[88]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Individuals using laxatives or stool softeners on a regular basis, especially outside the context of professional supervision, should be encouraged to increase their consumption of fresh fruits and vegetables as a means of preventing or reversing nutrient depletion. Repeated use of laxatives, other than bulking fibers such as psyllium seed husks, for longer than 7 days should be discouraged and root causal factors addressed. Healthful dietary practices will reduce the likelihood and severity of constipation and the need for laxatives or stool softeners in most individuals, especially when combined with increased intake of healthy oils and whole grains and regular exercise. Acute prophylactic potassium administration is judicious in some clinical situations, such as short-term use of laxatives before diagnostic procedures. Regular use of a high-quality multivitamin/mineral formulation will often be indicated and beneficial in preventing and correcting multiple nutritional insufficiencies in individuals using these medications, especially the elderly, institutionalized, or otherwise nutritionally compromised individuals. In general, nutritional supplements are most effectively assimilated when taken separate from fiber, mineral oils, or other substances that may potentially impair their absorption.

Losartan and Related Angiotensin II Receptor Antagonists

Evidence: Losartan (Cozaar), combination drug: losartan and hydrochlorothiazide (Hyzaar).
Extrapolated, based on similar properties: Candesartan (Atacand); combination drug: candesartan and hydrochlorothiazide (Atacand HCT); eprosartan (Teveten), irbesartan (Aprovel, Avapro, Karvea); combination drug: irbesartan and hydrochlorothiazide (Avalide); olmesartan (Benicar), telmisartan (Micardis), valsartan (Diovan); combination drug: valsartan and hydrochlorothiazide (Diovan HCT).

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

Probability:
2. Probable or
1. Certain

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Losartan and its active metabolite, E-3174, affect the renin-angiotensin system and reduce aldosterone activity by selectively blocking the binding of angiotensin II to angiotensin I receptors found in vascular smooth muscle and other tissues, causing vasodilation and inhibiting retention of sodium and water by the kidneys, thus decreasing blood volume. Neither losartan nor its active metabolite inhibits angiotensin converting enzyme, and, in fact, as these agents inhibit the pressor effect of angiotensin II the removal of the negative feedback of angiotensin II causes a significant rise in plasma renin activity, and a resultant rise in angiotensin II plasma concentration, in hypertensive patients. Consequently, losartan may cause increases in blood potassium levels that can be clinically significant.[94] Increasing potassium intake (food, supplements, prescription, salt substitute) concurrent with an angiotensin II receptor antagonist may lead to hyperkalemia and the resulting adverse effects.

Research

As the first angiotensin II receptor antagonist (ARB) to be marketed for the treatment of hypertension, losartan has

been the subject of more research than others drugs in this class. Nevertheless, "ARB-related hyperkalemia is class- and not compound-specific." Thus, as summarized by Sica[95] in a 2006 review of the effects of antihypertensive therapy on potassium homeostasis, that ARBs, as with ACE inhibitors, "will increase the serum K^+ value in virtually all treated subjects, but only to a degree (0.1-0.2 mEq/L) that is barely discernible clinically," and proposed that hyperkalemia in such cases "remains highly definitional in nature."

Hyperkalemia is a known adverse effect of losartan. In controlled hypertensive trials with losartan monotherapy and losartan-hydrochlorothiazide (Hyzaar), a serum potassium greater than 5.5 mEq/L occurred in 1.5% and 0.7% of patients, respectively.[96] Nevertheless, in such research no patient discontinued losartan or losartan-hydrochlorothiazide therapy because of hyperkalemia.[97] Moreover, in a study of the efficacy and tolerability of losartan in hypertensive patients with chronic renal insufficiency, Toto et al.[98] reported that hyperkalemia (>6 mEq/L) requiring discontinuation of losartan occurred in only one patient (of 112 subjects). However, in another study focusing on patients with type 2 diabetes and proteinuria, significantly more patients in the losartan group developed hyperkalemia (losartan 24.2% vs. placebo 12.3%; $p < 0.001$).[99]

Reports

Numerous reports, published and unpublished, describe hyperkalemia in patients receiving losartan or other angiotensin II receptor antagonist drugs, particularly in the context of potassium-sparing diuretics and compromised renal status.[100-105] Miyahara et al.[106] reported a case of intraoperative hyperkalemia induced with administration of an angiotensin II receptor antagonist and intake of dried persimmons, a fruit high in potassium.

Clinical Implications and Adaptations

Health care professionals treating patients taking an angiotensin II receptor antagonist (ARB) are strongly encouraged to counsel these individuals to avoid unsupervised increases in potassium intake, in the form of supplements but also as high-potassium foods (e.g., fruit) or salt substitutes, on the basis of the increased risk for problematic interactions. A clinically significant increase in blood potassium levels represents an uncommon yet potentially serious adverse effect associated with ARB drugs. The importance of frank inquiry and detailed inventory of concomitant (or even occasional) medications, diet, nutrients, and herbs cannot be overemphasized. Close supervision and regular monitoring are essential, especially in individuals with compromised renal function. The prescription of potassium chloride or potassium-sparing medications is generally contraindicated during angiotensin II receptor antagonist therapy.

Magnesium-Containing Antacids

5. Improbable

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Many anti-inflammatory agents affect potassium metabolism, but through a variety of mechanisms with the potential to produce a range of different effects, including severe reactions of rapid-onset hyperkalemia in acute renal failure. The effects of NSAIDs on prostaglandin production appear central to many adverse reactions. For example, indomethacin inhibits renal prostaglandin synthesis, which in turn reduces renin-aldosterone levels and potassium excretion and subsequently elevates serum potassium levels, potentially causing hyperkalemia. Similarly, ibuprofen can impair renal function and thus elevate blood potassium levels, particularly in elderly persons or those with preexisting renal compromise.[107] "Generally, the renal failure with NSAIDs is acute and reversible, though analgesic nephropathy with papillary necrosis and chronic renal failure are reported."[108]

Research

In a prospective, randomized, crossover trial, Whelton et al.[109] compared the renal effects of ibuprofen, piroxicam, and sulindac in patients with asymptomatic renal failure. "All three regimens suppressed renal prostaglandin production." In contrast to the other two NSAIDs, they observed excessive elevations of serum potassium by the eighth day (beyond those tolerated in the study design) that required withdrawal of treatment in 3 of 12 subjects who received ibuprofen, 800 mg three times daily. Further, when these three patients were rechallenged with ibuprofen, 400 mg three times daily, "two again developed evidence of acute renal deterioration." The authors concluded that "a brief course of ibuprofen, a compound widely used on a nonprescription basis, may result in acute renal failure in patients with asymptomatic, mild chronic renal failure."

Reports

Poirier[108] reported a "probable case of acute, reversible renal failure and hyperkalemia, after an increase in dose of ibuprofen." After reviewing other cases of renal dysfunction associated with NSAIDs, the author concludes: "Electrolytes, blood urea nitrogen, and serum creatinine levels need to be monitored in high-risk patients with predisposing factors and for chronic, long-term use of drugs that inhibit prostaglandin synthesis."

Clinical Implications and Adaptations

Potassium intake should be limited during NSAID therapy because potassium levels may rise in an unregulated manner, potentially reaching clinically significant hyperkalemia. Health care professionals treating patients using NSAIDs are strongly encouraged to counsel these individuals to avoid unsupervised increases in potassium intake, in the form of supplements but also as high-potassium foods (e.g., fruit) or salt substitutes, on the basis of the increased risk for problematic interactions. Although their use is widespread and largely unregulated, the high frequency of adverse reactions to NSAIDs is generally underestimated by patients and often forgotten by health care professionals. Apart from hepatotoxicity, which continues to be a major risk factor, the adverse effects of these agents on renal function need to be considered in all individuals with chronic use and even in some individuals with occasional use. A clinically significant increase in blood potassium levels represents an uncommon yet potentially serious adverse effect associated with NSAID therapy.

As previously noted, adverse reactions, although reversible, can be sudden and severe, particularly in those with compromised renal function. As summarized by Poirier[108]: "Possible predisposing factors to renal deterioration include the amount of drug consumed, presence of compromised renal blood flow, underlying renal insufficiency, nephrotoxic drug combinations, and high urinary prostaglandin excretion." Thus, regular monitoring is important in all patients using NSAIDs and close supervision may also be essential in those at high risk for adverse reactions. Principles of conservative practice recommend that health care professionals assess and correct the causes and aggravating factors involved in chronic inflammatory responses and educate patients to minimize use of anti-inflammatory medications.

Quinidine and Related Antiarrhythmic Drugs

Evidence: Quinidine (Quinaglute, Quinidex, Quinora).
Extrapolated, based on similar properties: Amiodarone (Cordarone), disopyramide (Norpace), dofetilide (Tikosyn), flecainide (Tambocor), ibutilide (Corvert), procainamide (Pronestyl, Procan-SR), sotalol (Betapace, Betapace AF, Sorine).
See also Digoxin and Related Cardiac Glycosides.

◉ **Emerging**

Effect and Mechanism of Action

The antiarrhythmic drugs with class 1A cardiac activity slow cardiac conduction and lengthen the QT interval. As with other antiarrhythmic drugs, quinidine may worsen cardiac rhythm disorders and increase the risk of death, especially in individuals with a history of a heart attack. More broadly, intracellular potassium and magnesium levels are intrinsic to electrical stability, and high and low levels of these anions, both within the cells and in the serum, predispose to cardiac rhythm disturbances; therefore, antiarrhythmic drugs of all classes (1A, 1C, and 3) can interact with medicines that affect potassium (and magnesium) levels.

Individuals with low blood levels of potassium (and magnesium), caused by diuretics, vomiting, or other stressors, may develop serious cardiac adverse effects, such as arrhythmias, in response to quinidine. In particular, quinidine causes torsades de pointes under certain conditions, particularly hypokalemia, hypomagnesemia, and other electrolyte abnormalities. Potent suppression of a potassium channel subunit current by quinidine is a likely contributor to torsades de pointes arrhythmias.[110] Thus, arrhythmias "may develop in hypokalemia due to enhanced normal automaticity, abnormal automaticity, or slowed conduction; moreover, hypokalemia is associated with enhanced digitalis toxicity, quinidine-related torsades de pointes, and interference with the antiarrhythmic activity of quinidine."[111]

With simultaneous intake, direct adsorption by potassium or other mineral salts could theoretically result in decreased drug bioavailability, although not necessarily to a clinically significant degree.[112]

Research

Hypokalemia, especially in the presence of hypomagnesemia or other electrolyte abnormalities, is associated with a range of adverse effects, including quinidine-related torsades de pointes, and interference with the antiarrhythmic activity of quinidine. Here, once again, the critical importance of the interrelationship between potassium and magnesium is a recurrent theme.

Mutations in a gene encoding a potassium channel subunit (HERG) can be related to the long-QT (LQT) syndrome characteristic of torsades de pointes, a polymorphic ventricular arrhythmia. Pharmacological suppression of repolarizing potassium currents is also a mechanism causing the acquired LQT syndrome.[110]

Roden and Iansmith[111] concluded their paper on the effects of low potassium or magnesium concentrations on isolated cardiac tissue by proposing that, in individuals with hypertension, "treatment that controls hypertension without causing electrolyte abnormalities is preferable for patients who are at risk of arrhythmias, or who are receiving drugs such as digitalis or quinidine."

Further research into electrolyte function in cardiac tissue, related drug interactions and depletions, and individual genomic and pharmacogenomic variability is warranted and can benefit from an integrative approach to multidisciplinary therapeutic interventions.

Report

Teplick et al.,[113] as well as other authors,[114] have reported cases of esophagitis caused by oral potassium chloride ("slow KCl" liquid and tablets) and quinidine tablets, separately. The concomitant use of these agents could theoretically increase the probability of adverse reactions. The authors noted that in "all reported cases caused by KCl tablets, left atrial enlargement was present as the result of mitral stenosis."[113]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing quinidine or related antiarrhythmic drugs, especially in conjunction with potassium-depleting diuretics, are advised initially to assess and then periodically monitor potassium and magnesium status, keeping in mind that serum concentrations do not accurately reflect intracellular levels. Coadministration of potassium and other nutrients may prevent or correct nutrient depletion that could create or amplify adverse drug effects. In contrast to magnesium, rapid repletion of potassium by the IV route is not used in the treatment of acute arrhythmias.

Within a comprehensive therapeutic repertoire, quinidine, potassium, and magnesium represent important options appropriate for consideration in crafting a long-term program of care for individuals with arrhythmias, hypertension, and other cardiovascular conditions. Treatment using medications that do not deplete vital nutrients or otherwise introduce electrolyte abnormalities is preferable, especially patients who at risk of arrhythmias or receiving drugs such as quinidine. Regular monitoring and appropriate nutritional support are important therapeutic tools when recourse to more deleterious agents is deemed necessary. Low potassium and magnesium concentrations not only contribute to or cause cardiac arrhythmias, but deficiencies of these minerals can also interfere with the efficacy or enhance the toxicity of many drugs used to treat patients with heart disease. Clinical care within an integrative setting might also emphasize a diet rich in vitamins, minerals, and antioxidants and incorporate hawthorn (*Crataegus oxyacantha*), L-carnitine, coenzyme Q10, and other nutrients as part of an individualized and evolving approach to cardiovascular therapeutics.

Spironolactone and Triamterene

Spironolactone (Aldactone); combination drug: spironolactone and hydrochlorothiazide (Aldactazide); triamterene (Dyrenium); combination drug: triamterene and hydrochlorothiazide (Dyazide, Maxzide).

Interaction Type and Significance

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

Probability:
2. Probable to
1. Certain

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

In contrast to potassium-wasting diuretics, spironolactone and triamterene, along with amiloride, constitute a drug class of diuretic agents that, by design, conserve potassium. Spironolactone inhibits the action of aldosterone and other mineralocorticoids, causing the kidneys to excrete sodium and fluid while retaining potassium. Triamterene achieves its diuretic effect by inhibiting the reabsorption of sodium in exchange for potassium and hydrogen ions in the distal renal tubule and thus maintains or increases sodium excretion and reduces loss of potassium, hydrogen, and chloride ions. Because triamterene is not a competitive antagonist of aldosterone, its dosing is determined by the kaliuretic effect of concomitantly administered drugs and the response of the individual patient, rather than being proportionate to the level of mineralocorticoid activity. Thus, triamterene can prevent diuretic-induced potassium loss comparable to 3.1 to 4.7 g (80-120 mmol) of potassium daily. Consequently, these medications are often used in combination with hydrochlorothiazide or other kaliuretic drugs to mitigate potassium wasting.

Conversely, increased potassium intake (foods, supplements, prescription, salt substitutes) could lead to excessive elevation of potassium levels in patients being treated with these medications, especially with concomitant ACE inhibitors or other medications that alter potassium metabolism. Arrhythmias and other adverse effects of hyperkalemia can be severe and are sometimes rapid in onset.

In addition to hypertension, potassium-sparing medications are used in the treatment of cirrhotic patients with ascites as well as those with Conn's, Bartter's, and Liddle syndromes and hirsutism.

Research

Spironolactone and triamterene intentionally reduce urinary excretion of potassium while enhancing sodium excretion. As potassium-sparing diuretics, these agents can produce a state of hyperkalemia (i.e., inappropriately elevated potassium levels). When used in combination with a thiazide diuretic, hyperkalemia (>5.4 mEq/L) has been reported as ranging from 4% in patients less than 60 years of age to 12% in patients 60 years and older, with an overall incidence of less than 8%. Arrhythmias and other cardiac irregularities are among the adverse effects associated with hyperkalemia. Conversely, concern has been raised about potential risks of hypokalemia among some patients using triamterene, even though hypokalemia is a less common occurrence with the use of triamterene than with non-potassium-sparing diuretics.

In a random crossover study, Jackson et al.[115] investigated the influence of spironolactone (50 and 100 mg daily), triamterene (100 and 200 mg daily), potassium chloride (32 and 64 mmol daily), and placebo on plasma potassium and other variables in nine hypertensive patients taking bendrofluazide, a thiazide diuretic (10 mg daily). They observed that spironolactone and triamterene had "significant and parallel dose-response curves for plasma potassium, with a relative potency for triamterene:spironolactone of 0.25:1, significantly lower than the accepted 0.5:1 ratio," while also lowering serum sodium, bicarbonate, and body weight and increasing serum urea and creatinine levels. Potassium chloride "increased plasma potassium above placebo values, but the dose-response was not significant and was not parallel with those of the potassium-sparing drugs." Notably, seven of nine patients "remained hypokalaemic despite treatment with 64 mmol potassium chloride daily."

Sawyer and Gabriel[116] studied progressive hypokalemia in 80 elderly patients with heart failure taking three thiazide potassium-sparing diuretic combinations over 36 months. Compared with amiloride and spironolactone, the "triamterene-containing preparation was discontinued most frequently (6/44) because of hypokalaemia (plasma potassium less than 3.0 mmol/L)." The median fall in plasma potassium over 3 years in those patients not withdrawn because of hypokalemia was "similar in each case (P greater than 0.05) and possibly failed to reach significance because of the withdrawal rate (9%)," and the "trend was for a greater fall in those patients taking triamterene." The authors concluded that the "spironolactone-containing preparation may be the least unsatisfactory of the three."

In a randomized study, Schnaper et al.[117] evaluated the efficacy of three drug regimens (hydrochlorothiazide and 20 mmol potassium; hydrochlorothiazide and 40 mmol potassium; or hydrochlorothiazide and triamterene) in patients rendered hypokalemic by hydrochlorothiazide while maintaining blood pressure control. Among 447 hypertensive patients, most with a history of diuretic-induced hypokalemia, 252 developed diuretic-induced hypokalemia while receiving hydrochlorothiazide (50 mg/day). In all groups, mean serum levels of potassium increased within 1 week and "showed no further change thereafter." Although each "regimen provided continued control of mild to moderate hypertension," the hydrochlorothiazide/triamterene and hydrochlorothiazide plus 40 mmol of potassium combinations were "significantly more effective in

restoring serum potassium levels" than was the combination of hydrochlorothiazide and 20 mmol of potassium. Furthermore, the authors reported that "significant increase in magnesium levels was observed only in the group treated with the hydrochlorothiazide/triamterene combination."

Reports

In at least one case, reported by Stepan et al.,[118] a patient has caused unintended hyperkalemia (and diarrhea) through surreptitious ingestion of potassium-sparing diuretics, with attendant decreased sodium absorption and elevated serum aldosterone levels.

Clinical Implications and Adaptations

Health care professionals treating patients with a potassium-sparing diuretic are strongly encouraged to counsel these individuals to avoid unsupervised increases in potassium intake, in the form of supplements but also as high-potassium foods (e.g., fruit) or salt substitutes, on the basis of the increased risk for problematic interactions. A clinically significant increase in blood potassium levels represents a potentially serious adverse effect associated with potassium-sparing diuretics. The importance of frank inquiry and detailed inventory of concomitant (or even occasional) medications, diet, nutrients, and herbs cannot be overemphasized. Close supervision and regular monitoring are essential, particularly when coadministered with an ACE inhibitor or in individuals with compromised renal function.

Trimethoprim-Sulfamethoxazole

Sulfamethoxazole and trimethoprim (cotrimoxazole, co-trimoxazole, SXT, TMP-SMX, TMP-sulfa; Bactrim, Bactrim DS, Cotrim, Septra, Septra DS, Sulfatrim, Uroplus). Related: Sulfamethoxazole (Gantanol), trimethoprim (Proloprim, Trimpex).

Interaction Type and Significance

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

Probability:
3. Possible or
2. Probable

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Trimethoprim or trimethoprim-sulfamethoxazole (TMP-SMX) may elevate potassium concentration, possibly to the point of hyperkalemia, which although reversible may be severe; these agents also can increase serum creatinine and BUN.[94,119-121] "Trimethoprim (an organic cation) acts like amiloride and blocks apical membrane sodium channels in the mammalian distal nephron."[120] Inhibition of sodium channels in A6 distal nephron cells by trimethoprim appears to play a role in the drug's potassium-sparing diuretic activity.[120] Consequently, the transepithelial voltage is reduced and potassium secretion inhibited, resulting in decreased renal potassium excretion and hyperkalemia.

Research

A small but consistent body of research findings indicates that trimethoprim or TMP-SMX can elevate potassium levels and tend to cause hyperkalemia, particularly in patients with compromised renal function or other major medical problems (e.g., AIDS).

Over several years, Velazquez, Alappan, Perazella, et al.[120-123] have conducted a series of trials and published several papers examining the issue of hyperkalemia during TMP-SMX therapy. In conjunction with a rodent experiment, they investigated the effects of trimethoprim-containing drugs on sodium channels in the distal nephron and renal potassium excretion in 30 patients with acquired immunodeficiency syndrome (AIDS). They found that trimethoprim "increased the serum potassium concentration by 0.6 mmol/L (95% CI, 0.29 to 0.95 mmol/L) despite normal adrenocortical function and glomerular filtration rate," and that 15 of the 30 subjects exhibited serum potassium levels greater than 5 mmol/L during trimethoprim treatment.[120] In a prospective chart review of 105 hospitalized patients with various infections, 80 of whom were treated with standard-dose TMP-SMX, they observed that serum potassium concentration in the treatment group increased about 5 days after TMP-SMX therapy was initiated. In contrast, the serum potassium concentration in the control group decreased nonsignificantly over 5 days. Thus, they reported that standard-dose TMP-SMX therapy used to treat various infections "leads to an increase in serum potassium concentration," based on the findings that a "peak serum potassium concentration greater than 5.0 mmol/L developed in 62.5% of patients; severe hyperkalemia (peak serum potassium concentration > or = 5.5 mmol/L) occurred in 21.2% of patients." They concluded that patients treated with standard-dose TMP-SMX "should be monitored closely for the development of hyperkalemia, especially if they have concurrent renal insufficiency (serum creatinine level > or = 106 μmol/L)."[122] Subsequently, in a prospective, randomized clinical study involving 97 outpatients, they investigated the effect of standard-dose TMP-SMX combination treatment on serum potassium concentrations. They observed that after 5 days, subjects receiving TMP-SMX (TMP, 320 mg/day; SMX, 1600 mg/day) "developed a statistically significant rise in the serum potassium concentration as compared with the control group," who received other antibiotics. "However, severe hyperkalemia ($K^+ \geq 5.5$ mmol/L) occurred in only 3 patients (6%) treated with trimethoprim-sulfamethoxazole," and "none of the subgroups of treated patients developed clinically important hyperkalemia." The authors interpreted these findings as suggesting that "outpatients, in contrast to [AIDS] patients and hospitalized patients with mild renal insufficiency, develop severe or life-threatening hyperkalemia less commonly when treated with this antimicrobial regimen." Nevertheless, they cautioned that "outpatients having risk factors which may predispose to the development of hyperkalemia should be carefully monitored" when treated with TMP-SMX.[123]

Reports

Hyperkalemia has been reported in patients receiving high-dose trimethoprim as well as standard-dose TMP-SMX therapy.[119,120,124] Velazquez et al.[120] and Greenberg et al.[119] described increases in serum potassium concentration of 0.6 mmol/L and 1.1 mmol/L., respectively, in AIDS patients administered high-dose trimethoprim (20 mg/kg/day). Three other cases of hyperkalemia in elderly patients receiving standard-dose TMP-SMX therapy were subsequently reported.[125-127] Koc et al.[128] published a case report of severe hyperkalemia in two renal transplant recipients treated with standard-dose TMP-SMX.

Clinical Implications and Adaptations

Physicians prescribing trimethoprim or TMP-SMX are strongly encouraged to counsel these individuals to avoid unsupervised increases in potassium intake, in the form of supplements but also as high-potassium foods (e.g., fruit) or salt substitutes, on the basis of the increased risk for problematic interactions. A clinically significant increase in blood potassium levels represents a potentially serious adverse effect associated with trimethoprim or TMP-SMX therapy. The importance of frank inquiry and detailed inventory of concomitant (or even occasional) medications, diet, nutrients, and herbs cannot be overemphasized. Close supervision and regular monitoring are essential, particularly with long-term use in individuals with compromised renal function or other significant physiological burdens and those taking other medications that might alter potassium metabolism.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Acetylsalicylic Acid (Aspirin)

Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Similar properties: Salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab).

High-dose aspirin may cause hypokalemia.[129] The effects of chronic aspirin intake on potassium status have not been documented. Clinically significant adverse effects are improbable in otherwise-unmedicated individuals with a well-balanced diet rich in fruits and vegetables, but are possible in the context of other risk factors, such as declining function with physiological aging, diet poor in nutrients and high in processed foods, comedication with potassium-depleting medications, or individual pharmacogenomic variations affecting any of these influences.

Amphetamines and Related Stimulant Medications

Amphetamine aspartate monohydrate, amphetamine sulfate, dextroamphetamine saccharate, dextroamphetamine sulfate; D-amphetamine, Dexedrine; combination drug: mixed amphetamines: amphetamine and dextroamphetamine (Adderall; dexamphetamine).

Amphetamine may theoretically disrupt potassium channels and thereby contribute to some of the adverse cardiac effects associated with these drugs.[130,131] However, potassium channel function and dietary intake of potassium are not necessarily related. Focused research with well-designed clinical trials may be warranted to determine the existence, probability and circumstances, severity, and clinical significance of any such interaction.

Calcium Channel Blockers

Amlodipine (Norvasc); combination drug: amlodipine and benazepril (Lotrel); bepridil (Bapadin, Vascor), diltiazem (Cardizem, Cardizem CD, Cardizem SR, Cartia XT, Dilacor XR, Diltia XT, Tiamate, Tiazac), felodipine (Plendil); combination drugs: felodipine and enalapril (Lexxel); felodipine and ramipril (Triapin); gallopamil (D600), isradipine (DynaCirc, DynaCirc CR), lercanidipine (Zanidip), nicardipine (Cardene, Cardene I.V., Cardene SR), nifedipine (Adalat, Adalat CC, Nifedical XL, Procardia, Procardia XL); combination drug: nifedipine and atenolol (Beta-Adalat, Tenif); nimodipine (Nimotop), nisoldipine (Sular), nitrendipine (Cardif, Nitrepin), verapamil (Calan, Calan SR, Covera-HS, Isoptin, Isoptin SR, Verelan, Verelan PM); combination drug: verapamil and trandolapril (Tarka).

See also Angiotensin-Converting Enzyme (ACE) Inhibitors and Beta-Adrenoceptor Antagonists.

Calcium signaling appears to play a role in both renal and external handling mechanisms involved in potassium regulation. Both verapamil and nifedipine, at pharmacological doses, can impair aldosterone production, but chronic administration of verapamil (but not nifedipine) appears to attenuate aldosterone responsiveness to angiotensin II in vivo after potassium loading. Calcium channel blockers may improve extrarenal potassium disposal. In a review (1991) of the effects of calcium channel blockers on potassium homeostasis Freed et al.[132] noted: "Clinically, there are no reports of either hyperkalemia or hypokalemia with the routine therapeutic use of these agents given alone." The authors concluded that review of the "data indicates that current evidence implicating this class of drugs in the pathogenesis of disordered potassium regulation remains equivocal." The authors reported the "development of hyperkalemia in a patient with chronic renal failure following the initiation of therapy with the calcium channel blocker diltiazem: however, numerous other etiologies may also have contributed to the development of hyperkalemia in this case."

Lavin et al.[37] examined the effect of 6 months' nifedipine (or captopril) therapy on lymphocyte magnesium and potassium levels in 28 patients treated for hypertension. They observed "no difference in serum or lymphocyte concentrations in the two groups compared to 45 healthy, normotensive controls."

Epinephrine and Related Beta-Adrenergic Agonists

Ephedrine (Adrenaline, Epi; Adrenalin, Ana-Gard, Asthma-Haler, AsthmaNefrin, Bronchaid, Bronkaid Mist, Brontin Mist, Epifin, Epinal, EpiPen, Epitrate, Eppy/N, Medihaler-Epi, Primatene Mist, S-2, Sus-Phrine; epinephrine, injectable: Adrenalin Chloride Solution, EpiPen Auto-Injector.

Based on the function of epinephrine/adrenaline as a "stress hormone," some secondary literature has suggested that elevated levels may reduce intracellular concentrations of potassium and magnesium and thus could be associated with hypokalemia.[133] In some discussions, adrenaline and beta-adrenergic agonists are lumped together, even though adrenaline is both an alpha-adrenergic and a beta-adrenergic agonist. Moreover, patients almost never use adrenaline on an ongoing basis; it is almost exclusively used in allergic reactions and other acute care situations, with the possible exception of Primatene mist (inhaled adrenaline OTC drug), which has been linked to asthma deaths, presumably from arrhythmias. Evidence from clinical trials or qualified case reports is lacking, and proposed mechanisms have not been

confirmed in relation to exogenous intake of epinephrine as a pharmaceutical agent.

Pending substantive research findings, it seems prudent that individuals using epinephrine on a repeated basis be counseled to maintain a diet high in potassium (as well as vitamin C and magnesium) or should consider regular use of a multinutrient formulation containing these nutrients. In general, close supervision and regular monitoring are warranted in patients prescribed adrenaline or related beta-adrenergic agonists, particularly with repeated use in individuals with compromised renal function, a history of cardiac irregularities or other significant physiological burdens, and taking other medications that might alter potassium metabolism.

Fluoroquinolone (4-Quinolone) Antibiotics

Cinoxacin (Cinobac, Pulvules), ciprofloxacin (Ciloxan, Cipro), enoxacin (Penetrex), gatifloxacin (Tequin), levofloxacin (Levaquin), lomefloxacin (Maxaquin), moxifloxacin (Avelox), nalidixic acid (Neggram), norfloxacin (Noroxin), ofloxacin (Floxin, Ocuflox), sparfloxacin (Zagam), trovafloxacin (alatrofloxacin; Trovan).

Several minerals can decrease the absorption of fluorinated quinolone antibiotics by chelating with these antibiotics when administered simultaneously. In such situations, the antimicrobials appear to be rendered inactive when the 3-carbonyl and 4-oxo functional groups characteristic of medications in this class form chelates with multivalent metal cations, particularly aluminum, magnesium, calcium, iron, and zinc, but also copper, manganese, and possibly sodium.

There is general agreement as to the pattern of interaction between fluoroquinolones and multivalent cations, as discussed in the monographs for several minerals. However, no published research (case reports or clinical trials) has specifically found that potassium acts in this way or adversely affects fluoroquinolone antibiotics by any other known mechanism.

Nevertheless, physicians prescribing fluoroquinolone antibiotics should instruct patients to take any mineral supplements (as well as related antacids) as far apart as possible from the medications, although a margin of at least 6 hours before or 2 hours after the antibiotics is usually adequate, to avoid the potential interaction. It is important to note that this interaction concern is only relevant to oral administration of both agents.

Haloperidol (Haldol)

Haloperidol (Haldol)

Haloperidol has variously been observed to induce both hyperkalemia and hypokalemia.[134,135] The clinical significance of changes in potassium concentrations due to haloperidol remains unclear, and specific evidence from relevant clinical trials is lacking.

Physicians prescribing haloperidol should consider disturbances in potassium metabolism and status among the potential adverse effects discussed with patients and monitored during therapy. Physicians should caution against rapid increases or decreases in potassium intake, from supplements, salt substitutes, or food sources (e.g., fruit), and any significant changes in potassium intake should be professionally supervised. The limitations of using serum potassium levels to detect intracellular potassium concentrations should be kept in mind when watching for adverse drug reactions.

Heparin

Heparin (Calciparine, Hepalean, Heparin Leo, Minihep Calcium, Minihep, Monoparin Calcium, Monoparin, Multiparin, Pump-Hep, Unihep, Uniparin Calcium, Uniparin Forte).

Related but evidence lacking for extrapolation:

Heparinoids: Danaparoid (Orgaran), fondaparinux (Arixtra).

Low-molecular-weight heparins: Ardeparin (Normiflo), dalteparin (Fragmin), enoxaparin (Lovenox), tinzaparin (Innohep).

Heparin therapy may increase serum potassium levels and has been associated with hyperkalemia.[94,136] Physicians administering heparin are advised to consider potential elevations in potassium levels and caution against rapid increases or decreases in potassium intake, from supplements, salt substitutes, or food sources (e.g., fruit). Any significant changes in potassium intake should be professionally supervised. Focused research with well-designed clinical trials may be warranted to determine the existence, probability and circumstances, severity, and clinical significance of any such interaction.

Insulin

Animal-source insulin: Iletin; human analog insulin: Humanlog; human insulin: Humulin, Novolin, NovoRapid, Oralin.

Matsumura et al.[137] reported the case of 47-year-old man with type 2 diabetes mellitus who experienced severe electrolyte disorders (including hypokalemia, hypophosphatemia, and hypomagnesemia) after attempting suicide by subcutaneously injecting a massive dose (2100 U) of insulin. Although this unique and extreme incident appears to carry minimal relevance to typical diabetic patients, this report has been mentioned as an example of a potential interaction between insulin and potassium. Pending well-qualified case reports or other scientific data indicating clinically significant interactions, further research does not seem warranted.

Notably, one of the standard treatments for life-threatening hyperkalemia is administration of glucose and insulin, which moves large amounts of potassium from the serum to the intracellular compartment to assist in rapidly lowering serum potassium.

Pseudoephedrine, Phenylpropanolamine, and Related Decongestants

Phenylpropanolamine (Acutrim, Dex-A-Diet, Dexatrim, Phenldrine, Phenoxine, PPA, Propagest, Rhindecon, Unitrol); combination drugs: Ami-Tex LA, Appedrine, Contac 12 Hour, DayQuil Allergy Relief, Dex-A-Diet Plus Vitamin C, Diadex Grapefruit Diet Plan, Dimetapp, Entex LA, Robitussin CF, Tavist-D, Triaminic-12.

Pseudoephedrine (Afrinol, Cenafed, Chlor Trimeton, Decofed, Dimetapp Decongestant, Drixoral, Efidac, Genaphed, PediaCare Infant Drops, Ridafed, Sudafed, Sudrine, Suphedrin, Triaminic A.M.).

Unsupported statements scattered through secondary literature mention the possibility of hypokalemia being associated with use of pseudoephedrine, phenylpropanolamine, and related decongestants. Published evidence from clinical trials is lacking to substantiate the occurrence of any such interaction, as is documentation of any proposed or proven mechanism of action.

The sympathomimetic effects of these medications may be similar to effects of the beta-2 agonists.

Tetracycline Antibiotics

Demeclocycline (Declomycin), doxycycline (Atridox, Doryx, Doxy, Monodox, Periostat, Vibramycin, Vibra-Tabs), minocycline (Dynacin, Minocin, Vectrin), oxytetracycline (Terramycin), tetracycline (Achromycin, Actisite, Apo-Tetra,

Economycin, Novo-Tetra, Nu-Tetra, Sumycin, Tetrachel, Tetracyn); combination drugs: chlortetracycline, demeclocycline, and tetracycline (Deteclo); bismuth, metronidazole, and tetracycline (Helidac).

Potassium may interact with tetracycline antibiotics in several ways. As with many minerals, but not as strongly as others, potassium may form chelates with tetracyclines, thereby impairing absorption of both agents. Tetracycline may interfere with the activity of potassium. Finally, self-limiting esophagitis and renal damage, adverse effects associated with tetracyclines, may be aggravated by concomitant potassium or may produce hyperkalemia from nephrotoxic effects, respectively.[113,114,138]

In 1965, Mavromatis[139] published a case describing tetracycline-induced nephropathy confirmed by renal biopsy. This apparently unique report has germinated a concern that tetracycline might cause hypokalemia because of its nephrotoxic effects. Evidence to substantiate this as an adverse event of any frequency is lacking but reinforces the recurrent admonition to monitor renal function and watch for hyperkalemia in at-risk patients.

Teplick et al.,[113] as well as other authors, reported several cases of esophagitis caused by oral potassium chloride ("slow KCl" liquid and tablets), tetracycline capsules, and doxycycline capsules, separately.[114,138] The concomitant use of these agents could theoretically increase the probability of adverse reactions. The authors noted that in "all reported cases caused by KCl tablets, left atrial enlargement was present as the result of mitral stenosis."[113]

Only minimal evidence from clinical trials or qualified case reports is available documenting or substantiating these possible interactions. This lack of confirmation in the literature suggests that such interactions are rare and of minimal clinical significance.

Physicians prescribing tetracycline-class antibiotics for longer than 2 weeks are advised to monitor renal function closely in patients with compromised renal function. Clinically significant potassium depletion is improbable in most individuals with short-term use of these medications. It is generally recommended that tetracycline antibiotics be taken on an empty stomach, with a full glass of water, 1 hour before or 2 hours after ingestion of any supplements, food, or other drugs. However, separating intake of antibiotics from mineral intake may be particularly important given the propensity to chelation between minerals and many medications. Further, potassium chloride should generally be taken with plenty of water and an upright position maintained for at least 1 hour after ingestion to avoid esophageal irritation; other forms of potassium may be tolerated more readily.

Theophylline/Aminophylline and Related Beta-2 Sympathomimetics (Oral and Inhalant)

Dyphylline (Dilor, Lufyllin), fenoterol (Berotec), oxytriphylline (Choledyl), salbutamol (Airomir, Apo-Salvent), terbutaline (Brethaire, Brethine, Bricanyl), theophylline/aminophylline (Phyllocontin, Slo-Bid, Slo-Phyllin, Theo-24, Theo-Bid, Theocron, Theo-Dur, Theolair, Truphylline, Uni-Dur, Uniphyl); combination drug: ephedrine, guaifenesin, and theophylline (Primatene Dual Action).

Although still unresolved after contentious debate for over 20 years, it appears that beta-2 sympathomimetic drugs can affect potassium status to the point of inducing hypokalemia, but that clinically significant adverse effects are improbable in most individuals.[140] As summarized by Cayton[141] in a letter: "The beta2 receptor has an important role in potassium homoeostasis, and hypokalaemia is a physiologically and pharmacologically predictable consequence of treatment with beta2 sympathomimetic bronchodilator drugs, which has been well documented in normal and asthmatic subjects."

In a clinical trial involving four groups of four healthy young subjects each, Haalboom et al.[142] investigated the effects on plasma potassium after inhalation of fenoterolin, a beta-2 agonist. Plasma potassium levels decreased significantly in subjects from the three groups who received fenoterol, whereas levels were unchanged in the placebo group. Based on these preliminary findings, the authors cautioned: "Inhalation of beta 2-agonists may be dangerous, especially in patients under stress—e.g., during an acute asthmatic attack, when the plasma potassium concentration would already be subnormal as the result of raised circulating adrenaline levels."[142] However, in a series of published letters, Smith, Berkin, and others replied that although "it is not disputed that acute beta2 agonist administration lowers the plasma potassium, the clinical relevance of this is not established." Citing prior research, they added: "Perhaps more importantly, the effect of chronic beta2 agonist dosing on plasma K appears to be negligible."[143-145]

Physicians treating patients using beta-2 sympathomimetic bronchodilator drugs are advised to monitor potassium levels, keeping in mind that serum concentrations can reveal hypokalemia but do not accurately reflect intracellular levels, and to be watchful for indications of potassium deficiency. The risk of compromised potassium status is often already heightened in patients with asthma taking steroids or those being treated with digoxin/diuretics for congestive heart failure. Concomitant nutritional support with potassium and magnesium may be beneficial in many of these patients but requires professional supervision and regular monitoring, at least initially, and on a continued basis in any individuals with compromised renal function. Well-designed clinical trials investigating this potentially dangerous adverse effect may be warranted to determine the existence, probability and circumstances, severity, and clinical significance. Discovery, compilation, and analysis of qualified case reports are also warranted.

Thioridazine

Thiorodazine (Mellaril).

Ventricular arrhythmias associated with use of thioridazine in alcohol withdrawal may be caused by alterations in electrical activity within the heart.[146] Coadministration of potassium might reduce the incidence and severity of such adverse effects, but substantive evidence from clinical trials and qualified reports is lacking.

NUTRIENT-NUTRIENT INTERACTIONS

Magnesium and Magnesium-Containing Antacids

Magnesium carbonate combination drug: magnesium carbonate, aluminum hydroxide, alginic acid, and sodium bicarbonate (Gaviscon Extra Strength Tablets, Gaviscon Regular Strength Liquid, Gaviscon Extra Strength Liquid); magnesium hydroxide (Phillips' Milk of Magnesia MOM); combination drugs: magnesium hydroxide and aluminum hydroxide (Advanced Formula Di-Gel Tablets, Co-Magaldrox, Di-Gel, Gelusil, Maalox, Maalox Plus, Mylanta, Wingel); magnesium hydroxide and calcium carbonate (Calcium Rich Rolaids); magnesium hydroxide, aluminum hydroxide, calcium carbonate, and simethicone (Tempo Tablets); magnesium trisilicate and aluminum

hydroxide (Adcomag trisil, Foamicon); magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets).

Magnesium plays a critical role in potassium metabolism. The dynamic and interdependent relationship between potassium and magnesium is demonstrated throughout the literature examining the physiology, pharmacology, therapeutics, and interactions of these key minerals, most critically with regard to cardiac electrical activity.[147] Magnesium depletion may be a cause of potassium deficiency, and magnesium coadministration is often necessary to correct refractory potassium repletion.[51,148] However, administration of potassium may increase the need for magnesium intake. Conversely, increased magnesium intake may cause a fall in serum potassium concentrations unless potassium intake is also increased.

The risk of cardiac arrhythmias or adverse effects due to the depletion of or interaction between these electrolytes is heightened in individuals taking potassium-depleting diuretics or digoxin or otherwise at risk of developing potassium deficiency becasue of chronic diarrhea, vomiting, or other factors.[80,104] Physicians treating individuals with such elevated risk, especially those with cardiac irregularities, are advised to encourage patients to maintain a regular and ample intake of foods rich in potassium, particularly fruits and vegetables, and to avoid changes in intake of either nutrient, especially rapid increases of supplemental forms, outside the context of medical supervision and regular monitoring.

HERB-NUTRIENT INTERACTIONS

Diuretic Herbs

Botanical agents with a diuretic action may or may not inherently deplete potassium or other nutrients, and some, such as dandelion leaf *(Taraxacum)*, may actually enhance mineral levels. The plant part(s) used, preparation, dosage, and clinical context all influence the mechanism by which any single herb or botanical combination achieves diuresis and the degree of depletion of potassium or other electrolytes. In general, a huge gap exists between the collective clinical experience of trained prescribers of botanical medicines and the relevant scientific literature of well-designed, adequately powered clinical trials as well as qualified case reports. Nevertheless, such effects and the limitations in the available data are discussed here to a limited degree and more thoroughly in the monographs on the major plant medicines in clinical use.

Ipecac

Ipecac *(Cephaelis ipecacuanha)*.

Repeated use of ipecac as an emetic can excessively lower serum potassium levels.[149] Health care professionals treating individuals with eating disorders or engaged in unsupervised rapid weight loss programs should caution them regarding the potential adverse effects of electrolyte imbalances and potentially dangerous practices associated with bulimia and other eating disorders. Increased consumption of fruit and potassium-containing mineral formulations may be appropriate pending suspension of such behavior.

Licorice Root

Licorice root *(Glycyrrhiza glabra, G. uralensis, G. echinata, G. pallidiflora)*; carbenoxolone (CBX); deglycyrrhizinated licorice, DGL.

See also Licorice monograph.

Licorice root from several species has been used in various forms in the traditional practices of European, American, and Chinese herbal medicine for centuries, if not millennia, and has generally been regarded as safe with professional evaluation and supervision. Nevertheless, high-dose chronic intake of herbal products containing licorice with the glycyrrhizin constituent present can cause pseudoaldosteronism, in certain susceptible individuals, characterized by elevated blood pressure, hypokalemia, and fluid retention, resulting from mineralocorticoid activity. Intake of more than 1 g of glycyrrhizin daily, the amount in approximately 10 g of licorice root, is considered adequate to produce clinically significant adverse effects.[150] Consequently, individuals with a history of or predisposition to hypertension are encouraged to use herbal medications containing non-deglycyrrhizinated (i.e., glycyrrhizin-containing) licorice (non-DGL) only under the supervision of health care professionals trained and experienced in herbal medicine and with active collaboration with the prescribing physician(s) whenever diuretics or cardiac medications are involved.

In contrast, licorice extracts that have been deglycyrrhizinated, and thus are typically labeled as "DGL," do not induce these effects, nor do most of the "licorice" confectionary products, because they generally do not contain actual licorice root.

Senna

Senna (*Cassia senna, Cassia angustifolia;* Black-Draught, Fletcher's Castoria, Gentlax, Senexon, Senna-Gen, Senokot, Senolax).

See Laxatives and Stool Softeners.

The 150 citations for this monograph, as well as additional reference literature, are located under Potassium on the CD at the back of the book.

Selenium

Nutrient Name: Selenium.
Elemental Symbol: Se.
Related Substances: Seleocysteine, selenomethionine; selenium aspartate; sodium selenite.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Chemotherapy ⊕⊕/☼	Selenium, as part of an antioxidant formulation, appears to reduce adverse effects of chemotherapy in treatment of ovarian cancer, most likely by inducing oxidative stress and enhancing activity of glutathione peroxidase system. Further clinical trials warranted.	Coadministration appears to provide benefit without impairment of therapeutic efficacy.
Cisplatin ☼/⊕⊕	Selenium can reduce nephrotoxicity and adverse effects on white blood cells associated with cisplatin, apparently without inhibiting antineoplastic activity of cisplatin. Bioactivation of selenite into selenols is a glutathione-dependent process that enables formation of protective cisplatin-selenol complex.	Coadminister, with supervision and monitoring. High selenium levels required may be toxic. Watch for interference with drug activity.
Clozapine ≈≈≈	Clozapine may decrease selenium levels; this may contribute to adverse effects associated with the drug, including agranulocytosis, decreased glutathione, and effects on the heart.	Coadminister selenium at modest levels. Monitor.
Corticosteroids, oral ≈≈≈	Inflammatory conditions may be associated with low selenium status. High-dose oral corticosteroids increase urinary selenium loss and may lower plasma selenium levels. Selenium enhancement can also support immune function and reduce risk of oxidative DNA damage.	Coadminister selenium with extended high-dose oral corticosteroid therapy.
Doxorubicin ☼/◇≈≈	Selenium may reduce doxorubicin-induced cardiotoxicity without interfering with the drug's antiproliferative effect, possibly by increasing cardiac mitochondrial glutathione peroxidase activity and reducing myocardial malondialdehyde content. Coadministration, at typical doses, is considered nontoxic and unlikely to interfere with therapeutic action of doxorubicin.	Selenium may be more effective when given before doxorubicin exposure. Assess cardiac performance during treatment.
Oral contraceptives (OCs) ◇≈≈/≈≈≈	OCs may decrease selenium levels. Selenium enhancement might reduce oxidative DNA damage and genomic instability, thereby reducing risk of hormone-associated cancer.	Coadminister, especially with selenium-deficient diet.
Valproic acid ◇≈≈/≈≈≈/☼	Valproic acid may decrease plasma selenium levels. Concomitant selenium may enhance antioxidant activity, particularly glutathione peroxidase, and decrease drug-induced toxic effects (e.g., hepatotoxicity) related to oxidative metabolites.	Coadminister, especially in children.

NUTRIENT DESCRIPTION

Physiology and Function

Selenium is an essential trace mineral in the human body, even though it was generally considered a toxic element until the 1950s. Dietary intake of selenium largely determines selenium levels in the body, and the mineral is found in variable amounts in some foods depending on its presence in the soil. The various forms of selenium are absorbed differently in the digestive tract and are retained for different durations. L-(+)selenomethionine is most readily absorbed and exhibits a significantly slower whole-body turnover rate, especially compared with inorganic selenite. These metabolic characteristics provide for efficient use of the selenium contained in methionine.

Selenium plays a key role in numerous metabolic pathways, most notably those exerting an antioxidant action. Selenium is metabolized to methylselenium and *S*-methylselenocysteine, its bioactive metabolites; it then acts at the level of nuclear transcription factors, signal transduction, cell cycle checkpoints, and cellular apoptosis. Selenium also appears to act as a substitute for sulfur in key signaling enzymes such as tyrosine kinase. In the form of selenocysteine, selenium is incorporated into selenoproteins, which play a central role in cellular antioxidant defenses and serve to neutralize free radicals and reduce risk of cancer and cardiovascular disease. In particular, *glutathione peroxidase* (GSH-Px, GPX), a selenium-dependent enzyme containing four atoms of selenium, recycles glutathione, reducing lipid peroxidation by catalyzing the reduction of peroxides, neutralizing hydrogen peroxide, and providing anti-inflammatory properties. Within several metabolic pathways, selenium acts as a cofactor, sometimes in the form of selenocysteine. Selenium also potentiates the antioxidant effects of vitamin E. Plasma selenium concentrations influence thyroid hormone levels, particularly the conversion of thyroxine (T_4) to the more active triiodothyronine (T_3), through its effect on the key regulatory enzyme iodothyronine deiodinase; lowered selenium levels are associated with impaired peripheral conversion of T_4 to T_3. Selenium's role in thyroid hormone activation exerts a special role in peripheral tissues. Thioredoxin reductase, a selenium- and NADPH-dependent flavoenzyme, is involved in intracellular reduction of substrates and appears essential to the mineral's anticancer activity. Selenium also participates in immune and detoxification functions by increasing T lymphocytes, enhancing natural killer cell activity, regulating production of immunoglobulin G (IgG) and tumor necrosis factor, and detoxifying heavy metal toxins, including mercury and cadmium.

The effects of selenium deficiency have been brought into focus through epidemiological studies in areas where the soil is particularly lacking in selenium, most notably the Chinese province of Keshan and Finland. Thus, the multifocal myocarditis of Keshan disease provides a stark study of the pathogenesis and pathology of frank selenium deficiency. Elevated rates of cancer in Finland exemplify the strong association between low dietary intake of selenium and increased risk of malignant disease. Diets high in

processed foods are similarly depleted of selenium. Numerous studies have documented an association between selenium intake and serum concentrations and the risk and severity of a wide range of cancers. Other symptoms of selenium deficiency include destructive changes to the heart and pancreas, pseudoalbinism, macrocytosis, increased red blood cell (RBC) fragility, immune system dysfunction, myositis, elevated creatine kinase derived from muscles, whitening of the fingernail beds, and a peculiar form of osteoarthropathy known as Kashin-Beck disease.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Apart from treatment of deficiency patterns, selenium is most widely known and universally respected as a cancer-preventive nutrient. Although not generally considered an antioxidant per se, selenium forms an integral part of the antioxidant system related to the superfamily of antioxidant enzymes that includes glutathione perioxidase (GSH-Px). Selenium's antioxidant role is critical in many ways, but its cytotoxic and antitumor activities cannot be wholly attributable to such properties. Maximal GSH-Px activity requires only minimal amounts of selenium. Significantly higher levels of selenium, approximately 10 times as much, are necessary to reach levels at which this trace element begins to exercise its cancer prevention effects.[1]

Historical/Ethnomedicine Precedent

Selenium has not been used historically as an isolated nutrient.

Possible Uses

Asthma, atherosclerosis, cardiac arrhythmia, cardiomyopathy, cataracts, childhood infectious diseases, colorectal cancer (risk reduction), depression, dermatitis herpetiformis, diabetic retinopathy, Down syndrome, food intolerance, gingivitis, human immunodeficiency virus and acquired immunodeficiency syndrome (HIV/AIDS) support, hepatitis, heavy metal toxicity, hospital-acquired infections in very-low-birth-weight infants (preventive), hypothyroidism, liver cirrhosis, lung cancer (risk reduction), macular degeneration, Osgood-Schlatter disease, pancreatic insufficiency, Pap smear (abnormal), parenteral nutrition (adjunctive), phenylketonuria (if deficient), prostate cancer (risk reduction), rheumatoid arthritis, retinopathy, surgery preparation/recovery support.

Dietary Sources

Brazil nuts are the single best food source of selenium. Herring, tuna, sardines, calf liver, soybeans, yeast, garlic, and eggs are good sources. Whole grains, especially wheat, can be excellent dietary sources of selenium but provide variable amounts depending on selenium levels in soil where cultivated.

Nutrient Preparations Available

Selenomethionine, selenocysteine, selenium-rich yeast, and selenium aspartate are organic forms of selenium and are preferable. Sodium selenite is the primary inorganic form of selenium and is generally considered less bioavailable.

Dosage Forms Available

Tablet, injection.

Source Materials for Nutrient Preparations

Yeast; organic selenium, selenite.

Dosage Range

Adult

Dietary: Average U.S. daily intake: 100 µg/day.
Supplemental/Maintenance: An adult intake of 100 to 300 µg/day is often recommended, depending on exposure to environmental toxins and individual risk assessment.
Pharmacological/Therapeutic: 50 to 200 µg/day, can be up to 1000 µg/day.
Toxic: Greater than 900 µg/day.

The U.S. National Academy of Sciences recommends that selenium intake not exceed 400 µg daily, unless the higher intake is monitored.[2] Daily intakes of up to 400 to 500 µg daily appear to be safe in healthy adults, although certain increased risks may be associated.

Note: Men apparently require higher levels of selenium intake than women, possibly because stores are lost with ejaculation.

Pediatric (<18 Years)

Pharmacological/Therapeutic: Usual dosage for children: 30 to 150 µg/day, or 1.5 µg per pound of body weight.

Laboratory Values

Blood Glutathione Peroxidase Activity

Blood glutathione peroxidase (GSH-Px) activity is a sensitive assay. The GSH-Px activity of RBCs can be expressed as international units per gram of hemoglobin.

Activity less than 30 IU/g hemoglobin indicates deficiency.

Serum Selenium

Serum selenium levels are transient.
Normal range is 0.9-1.9 µmol/L.

Many clinicians consider blood and urinary levels as inadequate indicators of selenium intake and tissue levels.

SAFETY PROFILE

Overview

Selenium has a narrow margin of safety. Although it is generally considered safe at typical supplement levels of 100 to 200 µg/day; 800 µg/day is probably the highest long-term daily dose that can be taken without the development of toxicity in most people. There are variations in the toxic dose, as with other nutrients, but selenium must be used with caution. Daily dosages exceeding 900 µg have been associated with adverse effects in some individuals.[3] Estimates from cattle and other animals show that the toxic long-term dose is probably closer to 2.4 to 3 mg/day. This would lead to symptoms such as liver, skeletal, and cardiac muscle damage.

General Adverse Effects

High blood levels of selenium can result in a condition called *selenosis*.

Dosages greater than 1000 µg of selenium daily for an extended period have been associated with toxic signs that include depression, nervousness, emotional instability, lethargy, weight loss, nausea, vomiting, garlic-like breath and sweat, metallic taste in mouth, digestive irritation, peripheral

neuropathies, dermatitis, hair loss, loss of teeth, and fingernail damage or loss. Rare cases of thrombocytopenia and hepatorenal dysfunction have been reported.

Signs and symptoms of severe overdose include fever, increased respiratory rate, gastrointestinal (GI) distress, paralysis, myelitis, and, potentially in extreme cases, death.

There have been no reports of death attributed to selenium toxicity in humans; however, fatal overdoses have been reported in livestock. Reports of selenium overdose in humans indicate resolution of adverse effects on cessation of intake.

Limited secondary research suggests that supplemental intake of selenium, 200 µg/day, for 7.7 years (average) may be associated with an increased risk of developing type 2 diabetes mellitus.[3a]

Contraindications

Individuals with low thyroid function or iodine deficiency–induced goiter are reported to be at an increased risk of symptom exacerbation with selenium supplementation.[4] Selenium supplementation in individuals with a history of nonmelanoma skin cancer may raise the risk of squamous cell cancer.[5]

High hair selenium levels in children have been associated with learning disabilities and behavioral problems.

INTERACTIONS REVIEW

Strategic Considerations

The wide-ranging roles of selenium in healthy human physiology and the well-known adverse effects of selenium deficiency warrant our attention as a valuable agent in health optimization and disease prevention, as well as a potentially critical ally in disease management using conventional pharmacology. In particular, clinicians must consider the selenium depletion patterns associated with many pathologies and suspected to be aggravated by some pharmacological agents. Selenium's role in cancer prevention has always suggested to clinicians that it might prove to be of therapeutic benefit as a component of cancer therapy. Although the direct treatment of cancer using selenium within an integrative model is just emerging, the use of selenium coadministration within a chemotherapeutic regimen has been the subject of extensive, but still often inconclusive, research. It has been widely demonstrated that alterations in selenium levels directly affect the concentration and activity of glutathione peroxidases. Results from animal experiments indicate that selenium compounds, as well as other antioxidant nutrients such as vitamin E, are protective against lethality and other radiation effects, although to a lesser degree than some synthetic protectors.[6] Further, the strong association recognized between selenium deficiency and cardiomyopathy suggests use of this crucial trace mineral in limiting known cardiotoxic effects of medications such as doxorubicin.

Many of the issues discussed reveal a need for human clinical trials, first to ascertain efficacy and then, on confirmation, to flesh out the particulars of integrative care models using the knowledge, skills, and experience of clinicians experienced in both conventional pharmacology and nutritional therapeutics. Researchers may find value in looking to studies such as the Polish clinical trial investigating selenium deficiency and concomitant administration of selenium (200 µg/day) and antioxidant nutrients for 3 months in women with ovarian cancer undergoing multidrug chemotherapy. Selenium nutrient coadministration was associated with significantly increased serum and hair concentrations of selenium and significantly higher activity of GSH-Px.[7] Further, Last et al.[8] retrospectively analyzed total selenium content in 100 sera of patients with aggressive B-cell non-Hodgkin's lymphoma who had received anthracycline-based chemotherapy, radiotherapy, or both. They determined that serum selenium concentration at presentation is a prognostic factor, predicting positively for dose delivery, treatment response, and long-term survival. The authors concluded that selenium supplementation might offer a novel therapeutic strategy in the treatment of aggressive non-Hodgkin's lymphoma.

NUTRIENT-DRUG INTERACTIONS

Chemotherapy (Cytotoxic Agents)

Evidence: Cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox).
Related but evidence lacking for extrapolation: Alkylating agents: Busulfan (Myleran), carboplatin (Paraplatin), chlorambucil (Leukeran), dacarbazine (DIC, DTIC, DTIC-Dome, imidazole carboxamide), ifosfamide (Ifex, Mitoxana), mechlorethamine (Mustargen, nitrogen mustard), melphalan (Alkeran), oxaliplatin (Eloxatin), phenylalanine mustard (Melphalan), pipobroman (Vercyte), streptozocin (Zanosar), temozolomide (Temodar), thiotepa (Thioplex), uracil mustard (uramustine).
See also Cisplatin and Doxorubicin

Interaction Type and Significance
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
2. Probable

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Selenium can reduce oxidative stress and enhance activity of the glutathione peroxidase (GSH-Px) system.

Research

Sieja and Talerczyk[9] found that selenium supplementation positively influences oxidative stress (as evidenced by lowered levels of the oxidative stress marker malondialdehyde), enhances the GSH-Px system, and decreases the morbidity of patients with ovarian cancer undergoing chemotherapy. Their study involved the proprietary formulation Protecton Zellactiv (Smith Kline Beecham, Fink Naturarznei GmbH). In a clinical trial involving 62 patients with ovarian cancer, after standard debulking surgery, all patients were treated with adjuvant cyclophosphamide and cisplatin chemotherapy. Half the patients were randomized to receive, concurrently with the chemotherapy, either the antioxidant formula containing beta-carotene (25,000 IU), vitamin C (200 mg), vitamin E (27 IU), riboflavin (4.5 mg), niacin (45 mg), and selenium (200 µg) or the same formula without selenium, for 3 months. Patients who received both the antioxidant vitamins and the selenium for 3 months were noted to have significant increases in serum selenium concentration, GSH-Px in erythrocytes (RBCs), and white blood cell (WBC) numbers and a decrease of hair loss, flatulence, abdominal pain, weakness, malaise, and loss of appetite.[9]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The encouraging findings from this small trial support the need for further large, well-designed clinical trials to investigate integrative therapeutic strategies using selenium with and without

other antioxidant nutrients (e.g., Protecton Zellactiv) in conjunction with chemotherapeutic agents. Safe and effective implementation of this therapeutic strategy requires close supervision and regular monitoring within the context of integrative care involving health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics.

Cisplatin

Cisplatin (*cis*-Diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ).
Extrapolated, based on similar properties: Carboplatin (Paraplatin), oxaliplatin (Eloxatin).

◉ **Emerging**

Effect and Mechanism of Action

Selenium appears capable of playing a protective role in the treatment of cancer patients by reducing the nephrotoxicity and WBC-lowering effects typically encountered as an adverse effect of chemotherapy regimens employing cisplatin. Cisplatin exerts its antitumor activity through an interaction with DNA, which results in the formation of bidentate adducts. An important adverse effect of cisplatin therapy is nephrotoxicity. Cisplatin also causes changes in selenium levels and GSH-Px activities. The protective effect observed with administration of selenium correlates with higher levels of selenium in the kidney (about eight times) and with higher levels of glutathione in the kidney, both compared to tumors. Selenite is metabolized into selenols, specifically into methylselenol and glutathionylselenol; this bioactivation of selenite into selenols is a glutathione-dependent process. Baldew et al.[10] proposed in 1991 that the formation of a cisplatin-selenol complex (from methylselenol) takes place in the kidney, thereby preventing cisplatin from exerting its nephrotoxic activity. Selenium may also bind with platinum and inactivate the antineoplastic platinum coordination complexes in a manner similar to sulfur, with which it shares many chemical properties.

Research

The research team led by Vermeulen and Baldew conducted a number of studies into the interaction between selenium and cisplatin. A paper published in 1988 reported cisplatin-induced changes of selenium levels and GSH-Px activities in blood of testis tumor patients.[11] The next year, in research using rodents, they determined that administration of sodium selenite (2000 µg/kg), 1 hour before cisplatin therapy, greatly reduced the nephrotoxic effects associated with the medication without altering antitumor activity.[12] In 1993 this team reported a reduction of cisplatin nephrotoxicity in rodents after administration of sodium selenite and noted a lack of interaction at the pharmacokinetic level of both compounds. Sodium selenite, in doses protecting against the nephrotoxicity of cisplatin, did not significantly affect areas under the plasma concentration-time curve (AUC) from 0 to 6 hours or the initial plasma half-lives of cisplatin and total platinum in plasma.[13] An animal study by Ohkawa et al.[14] Similarly found that sodium selenite reduced toxicity from cisplatin in mice.

In a randomized controlled trial with 41 subjects, Chinese researchers investigated the effects of Seleno-Kappacarrageenan, a selenium-containing formulation, as an agent for reducing the nephrotoxicity and bone marrow suppression induced by cisplatin. Administration of the selenium compound, at 4000 µg/day, in conjunction with a cisplatin regimen, resulted in significantly reduced kidney damage, significantly elevated peripheral WBC counts, and significantly less required volumes of blood transfusion compared with controls. Even though researchers observed no toxicity attributable to the Seleno-Kappacarrageenan, the dosage of selenium administered in this study would generally be considered as potentially toxic, if given frequently, and only appropriate under expertly supervised conditions.[15]

A study conducted in Finland, a country known for selenium-poor soil, investigated the potential benefits of selenium and vitamin E in conjunction with cytotoxic chemotherapy in the treatment of 41 women with ovarian cancer. The chemotherapy regimen consisted of cisplatin in combination with either doxorubicin and cyclophosphamide or melphalan. The 29 patients administered nutrients were divided into three groups receiving 200 µg/day sodium selenate, 300 mg/day vitamin E, or both. Sodium selenate alone and combined with vitamin E significantly increased the serum selenium levels, but the activity of serum glutathione peroxidase (GSH-Px) increased significantly only in the selenium-treated and vitamin E–treated patients with low initial GSH-Px activity. Sodium selenate alone significantly decreased the capacity of the platelets to produce thromboxane A_2 (which should result in decreased platelet activation); it also increased high-density lipoprotein cholesterol levels and prevented the elevation of creatine kinase typically associated with cytotoxic chemotherapy. The therapeutic benefits of selenium coadministration appeared to be particularly evident in patients with low initial selenium levels.[16]

In a 1997 review article, Olas and Wachowicz[17] concluded that administration of sodium selenite reduces cisplatin toxicity without inhibiting the antineoplastic activity of cisplatin. Nevertheless, some of the potentially efficacious effects of selenium, such as reducing myelosuppression, suggest the potential for interference with the antitumor activity of cisplatin. Further, sodium thiosulfate is routinely used to deactivate cisplatin. Some head and neck cancer protocols infuse cisplatin intra-arterially through a major artery perfusing the tumor, then inject sodium thiosulfate intravenously, to complex with and deactivate the drug once in the venous circulation. Given the interchangeability of selenium and sulfur, this could also apply to selenium, but since selenium's doses are orders of magnitude less than for sulfur, the stoichiometry would argue against selenium having major interference. This proposition deserves to be rigorously tested in well-designed randomized clinical trials with well-matched patient populations that are large enough to detect even modest gains or losses of therapeutic efficacy.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although selenium coadministration represents a valuable option for adjunctive use with cisplatin, the selenium dosages used in many of the cited studies represent a potentially toxic dosage level. Administration of selenium during chemotherapy using cisplatin and carboplatin warrants caution. Some of the potentially beneficial actions of selenium, such as reducing myelosuppression, suggest the as-yet unproven potential for interference with the action of platinum chemotherapy agents. Thus, safe and effective implementation of this

therapeutic strategy requires close supervision and regular monitoring within the context of integrative care involving health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics. The collective research findings indicate that selenium appears to be most efficacious when administered 1 hour before cisplatin therapy. Selenium dosage, form, and mode of administration should be determined based on the unique and evolving needs of the individual being treated in coordination with the overall therapeutic strategy. Daily dosages in the range of 200 to 600 µg are considered as generally effective and safe over an extended time. Much higher intermittent doses, up to 4 mg, given 1 hour before platinum chemotherapy, appear to be well tolerated, and are unlikely to lead to toxic accumulation of selenium, unless relatively high doses are also chronically administered.

Clozapine

Clozapine (Clozaril).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability:
2. Probable

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Clozapine use appears to decrease blood levels of selenium and may contribute to drug-related adverse effects, particularly agranulocytosis.

Research

In a cross-sectional pilot study, Linday et al.[18] investigated the possible role of abnormalities in the body's antioxidant defense system in the pathogenesis of clozapine-associated agranulocytosis, an uncommon adverse effect. They observed that plasma selenium levels were lowest in individuals undergoing clozapine therapy or experiencing postclozapine agranulocytosis; plasma GSH-Px levels were also lowest in the postclozapine agranulocytosis group. A subsequent study using a novel in vitro assay technique revealed that clozapine and its stable metabolites are not cytotoxic per se but are bioactivated to cytotoxic metabolites that may play a role in the pathogenesis of clozapine agranulocytosis. They noted that bioactivation of clozapine (and its metabolite demethylclozapine) was accompanied by depletion of intracellular glutathione.[19]

In a 2003 study, researchers gathered random venous blood samples to compare selenium levels in four groups: individuals diagnosed with mood disorder, schizophrenics treated with clozapine, schizophrenics not treated with clozapine, and a healthy control group. They found that selenium concentrations in plasma and RBCs were significantly lower in schizophrenic patients treated with clozapine compared with all other groups. The authors noted that low selenium concentrations in clozapine-treated patients may be important in the pathogenesis of life-threatening cardiac adverse effects associated with clozapine.[20]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The cumulative evidence indicates that clozapine may deplete selenium and glutathione, and that an association may exist between such status and susceptibility to clozapine-induced agranulocytosis. At this time, there is no conclusive evidence to confirm or negate the need for, or benefit from, selenium administration in individuals undergoing therapy with clozapine or other atypical neuroleptic medications. Given the protective antioxidant function of selenium in general and potentially in prevention of known adverse effects of clozapine, the conservative course of action would be to offer the patient the option of coadministering modest amounts of selenium (e.g., 100-200 µg/day) during clozapine therapy.

Corticosteroids, Oral

Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol) prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability:
2. Probable

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

High-dose oral corticosteroids increase urinary selenium loss and may lower plasma selenium levels. Some clinicians have also noted that individuals with chronic inflammatory conditions tend to have a preexisting compromised selenium status that would make them particularly susceptible to depletion by steroid medications.[21,22]

Research

Experimental and clinical studies suggest that selenium modulates inflammatory and immune responses. Low selenium levels are common among individuals with inflammatory rheumatic diseases, although such status does not correlate with disease severity. Peretz et al.[21,22] studied the plasma selenium levels, erythrocyte selenium levels, and activity of the selenoenzyme GSH-Px in erythrocytes of patients with rheumatoid arthritis (RA) and acute inflammatory arthritis. They determined that sustained oral corticosteroid therapy, particularly at high doses (20-60 mg prednisolone daily), was significantly related to the depressed plasma selenium levels of some patients with RA.[21,23]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Chronically low selenium levels are associated with diverse pathologies characterized by inflammation and immune dysfunction, including rheumatic disorders.[24] Deficiency of this trace mineral may lead to oxidative DNA damage.[25] The use of corticosteroid medications may further compromise selenium status in some treated individuals. Prevention of marginal selenium deficiency or reversal of steroid-induced depletion by moderate supplementation might enhance host defense mechanisms, facilitate symptom amelioration, and support systemic healing processes. Further research is needed to establish selection criteria and refine methods for ascertainment of appropriate dosage of selenium to obtain the desired stimulatory or inhibitory effect relevant to the disease state and therapeutic strategy. When prescribing glucocorticoid medications and seeking to invoke potential benefits of concomitant selenium, typical therapeutic dosages of selenium are in the range of 100 to 200 µg daily. At this time, no research appears to

indicate that concurrent selenium might interfere with the therapeutic action of steroid medications.

Doxorubicin and Related Anthracycline Chemotherapy

Evidence: Doxorubicin (Adriamycin, Rubex).
Extrapolated, based on similar properties: Daunorubicin (Cerubidine), epirubicin (Ellence, Pharmorubicin), idarubicin (Idamycin, Zavedos), mitoxantrone (Novantrone, Onkotrone).
Similar properties but evidence lacking for extrapolation: Dounorubicin, liposomal (DaunoXome); doxorubicin, pegylated liposomal (Caelyx, Doxil, Myocet).

Interaction Type and Significance

Effect and Mechanism of Action

Doxorubicin is a highly effective antineoplastic agent, but cardiotoxicity, acute and chronic, is an adverse effect occurring in up to one third of the patients treated after a cumulative dose of 300 mg/m^2, and increasing sharply beyond a cumulative dose of 360 mg/m^2. The resultant irreversible and dose-dependent cardiomyopathy limits its clinical usefulness. Doxorubicin's toxicity results in significant part from free-radical generation and the resultant oxidative stress. Selenium significantly reduces toxicity of doxorubicin without reducing its antitumor activity. Although inorganic selenium lacks direct antioxidant properties, the glutathione peroxidases and other circulating selenoproteins play a central role in cellular antioxidant functions. Selenium coadministration with drug delivery, typically as part of an antioxidant combination, can inhibit doxorubicin-induced decreases in myocardial vitamin E and GSH-Px, reduce oxidative stress, and reduce or prevent doxorubicin-induced cardiotoxicity.[26-28]

Cardiotoxicity of anthracycline chemotherapy agents is multifactorial and also involves oxidative stress partly mediated by an iron-catalyzed Fenton reaction; iron-chelating agents have been shown to decrease doxorubicin cardiac toxicity. Two conditions of cardiotoxicity have been recognized. The first is a dose-independent idiosyncratic phenomenon appearing immediately after anthracycline administration and is based on a pericarditis-myocarditis syndrome in patients without previous cardiac disease. The second condition is dose related and characterized by progressive decline of left ventricular systolic function, as assessed by the ejection fraction on nuclear medicine and echocardiographic studies, which may lead to congestive heart failure (CHF). Diastolic dysfunction may also lead to CHF, with or without concomitant compromise of left ventricular ejection fraction. On pathological examination, progressive anthracycline-related cardiac damage may include restrictive endomyocardial disease, characterized by fibrous thickening of the endomyocardium, and dilated cardiomyopathy, as a result of myocardial fibrosis and hypertrophy of surviving myocytes. Symptoms can appear many years after completion of chemotherapy, although sequential assessment of left ventricular systolic and diastolic function will show compromise long before symptomatic CHF ensues. Risk of anthracycline-induced CHF is increased by radiotherapy fields that involve all or part of the heart.[29-31]

Cardiac toxicity is similar between equipotent doses of doxorubicin and daunorubicin, slightly lower for epirubicin, and only one-sixth that of doxorubicin for equipotent doses of mitoxantrone. Doxil and DaunoXome (liposomal doxorubicin and daunorubicin, respectively) have negligible cardiotoxicity, presumably because of minimal cardiac exposure to the active drug with the pharmacokinetics of the liposome-encapsulated preparation.

Research

Within conventional oncology, the anthracycline antibiotic doxorubicin (Adriamycin) is considered one of the most effective chemotherapeutic agents against a variety of cancers, but its utility is seriously curtailed by its cardiotoxic action and the attendant risk of developing cardiomyopathy and heart failure. Studies investigating the possible beneficial role of selenium in relation to doxorubicin toxicity have focused on two issues: selenium deficiency in laboratory animals and the effects of selenium administration in several experimental models.

Most authors,[32-35] but not all,[36,37] have reported that in rats, selenium deficiency contributes to an aggravation of doxorubicin cardiotoxicity. In these animal studies, researchers mainly reported that toxic effects in selenium-deficient rats resulted from the effect of lipid peroxidation or free-radical generation on several direct or indirect mechanisms, including DNA oxidative damage and mitochondrial alterations.

Studies on selenium supplementation have focused on its anticancer effects or its effects on the cardiotoxicity of doxorubicin. In the latter regard, conclusions have varied in several animal models. Van Vleet et al.[38] failed to find any significant evidence of cardioprotection after injecting dogs with selenium during a course of doxorubicin. In a study using mice, Hermansen and Wassermann[39] reported that selenium provided no significant protection against toxic effects from intraperitoneal injections of doxorubicin. Researchers in other animal studies reported that selenium administration provided cardioprotective effects against doxorubicin-induced toxicity. Van Vleet and Ferrans[40] injected rabbits with both doxorubicin and selenium once a week for 17 weeks and found that rabbits thus treated with selenium showed improved survival rates and reduced symptoms of cardiomyopathy. Van Vleet et al.[41] described positive outcomes, including delayed onset of leukopenia and prolonged survival, after selenium was administered to pigs receiving doxorubicin for 13 weeks. Dimitrov et al.[42] found that selenium abrogated doxorubicin-induced cardiotoxicity in rabbits without interfering with the drug's antiproliferative effect. Examination of animals that had received selenium showed increased selenium levels in the plasma and the heart muscle, as well as preservation of normal heart histology.[42] Finally, Boucher et al.[43] demonstrated several positive responses indicating reduction in doxorubicin cardiotoxicity after treating rats injected with intraperitoneal doxorubicin, twice weekly for 3 weeks, with 3 weeks of oral selenium, using standard food enriched with 2500 µg selenium/kg. The animals given selenium showed significantly increased levels of cardiac mitochondrial GSH-Px activity, reduced myocardial malondialdehyde content, and no increase in the degree of structural alterations to sarcomeres induced by doxorubicin.

These mixed results may reveal more about variable responses to doxorubicin and selenium among different species, as well as the influence of different dosages, treatment lengths, and delivery forms of selenium, than about the anticancer or cardioprotective effects of selenium. Generally, selenium was more effective when given before doxorubicin exposure.

In an in vitro study, Vadgama et al.[44] investigated the effects of administering doxorubicin and selenium together to several tumor cell lines. They reported that selenium increased the doxorubicin effect in most of the cell lines, including increased levels of apoptosis and decreased DNA synthesis.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

In considering the paramount issue of doxorubicin-induced cardiotoxicity, the parameters of the individual patient's health status, risk factors, prognosis, and therapeutic preferences must be weighed within a process of informed decision making. Safe and effective implementation of this therapeutic strategy requires close supervision and regular monitoring within the context of integrative care involving health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics. Cardiac performance must be assessed before doxorubicin therapy begins, during treatment, and as part of regular follow-up after chemotherapy has concluded. The animal studies reviewed indicate that pretreatment selenium was more effective in limiting doxorubicin toxicity. Selenium dosage, form, and mode of administration need to be determined based on the unique and evolving needs of the individual being treated, in coordination with the overall therapeutic strategy. Daily dosages in the range of 200 to 600 µg are considered as generally effective and safe over an extended period. A conservative approach to clinical management suggests that selenium administration may provide protective influences and assist the therapeutic process, with little or no known risk that such nutrient coadministration might be toxic or interfere with the pharmacological action of the primary treatment.

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCept 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).

Effect and Mechanism of Action

Human research indicates that oral contraceptives (OCs) are associated with decreased serum selenium concentrations,[45] possibly attributable to interference with selenium absorption.

Research

Heese et al.[45] conducted a study in South Africa involving 200 female students, half of whom had been taking a low-dosage triphasic OC for a minimum of 3 months; the others were using no OCs. Women using OCs demonstrated differences in mean serum selenium concentrations that were statistically significant.

L'Abbe et al.[46] measured the activity of the enzyme glutathione peroxidase (SeGSHPx) as an indicator of selenium status in a large sample of healthy, free-living Canadians. They observed that estrogen use significantly elevated erythrocyte SeGSHPx, non-SeGSHPx, and total activities in both premenopausal and postmenopausal women.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although the evidence shows that OCs may be associated with decreased levels of selenium and other micronutrients, the clinical significance of these actions regarding cancer susceptibility and other health risks remains unclear. However, deficiency of this trace mineral may contribute to increased oxidative DNA damage and genomic instability and is considered a significant factor in setting the stage for carcinogenesis.[25] Given the ever-growing literature on the beneficial role of selenium in the prevention of cancer, especially breast cancer, the adverse implications of contraceptive-induced decreases in selenium levels become increasingly significant.

Apart from supplementation of selenium, intake levels primarily depend on the levels of selenium in the soil where foods have been grown. Health care professionals providing care to women using OCs may want to discuss the potential benefits of compensatory selenium intake and present clinical options. Many practitioners experienced in nutritional therapeutics recommend 100 to 200 µg of selenium as the appropriate daily adult dose for cancer prevention; such a dosage level would also be generally considered adequate to address the additional depletion pattern possible from OCs. However, the character of an individual's diet, geographic locale, family history, personal medical history and health status, and other aspects of individual susceptibility, particularly pharmacogenomic variability of estrogen sensitivity and liver metabolic processes, need to be considered in determining individual risk severity and the relative need for such nutrient support.

Valproic Acid

Divalproex semisodium, divalproex sodium (Depakote), sodium valproate (Depacon), valproate semisodium, valproic acid (Depakene, Depakene Syrup).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **4. Plausible**
Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Valproic acid (VPA) may decrease plasma selenium levels and interfere with related normal physiological functions

based on the medication's expected pharmacological actions. Researchers have produced mixed evidence as to the clinical significance of potential selenium (and glutathione) deficiency and its relative impact for different individuals and within different patient populations. Children undergoing anticonvulsant therapy using VPA may be particularly vulnerable to the hepatotoxicity and other adverse effects typically associated with the medication. Concomitant selenium intake may prevent or reduce adverse effects experienced by some individuals undergoing VPA therapy, at least in part by countering drug-induced depletion. Selenium-dependent antioxidant activity, particularly involving GSH-Px, appears to play a critical role in protecting against specific oxidative metabolites of VPA associated with the drug's toxicity.[47-49]

Research

Recent studies suggest that membrane lipid peroxidation may be causally involved in some forms of epilepsy, and that conventional anticonvulsant treatment may adversely affect selenium-dependent antioxidant systems. Although a significant body of evidence demonstrates that VPA adversely impacts selenium and glutathione levels, other researchers have reported minimal depletion of selenium and negligible clinical implications. Research indicates that VPA's cytotoxic activity is the result of generation of hydrogen peroxide and the production of highly reactive hydroxyl free radicals. Buchi et al.[50] found that the free-radical scavenging action of alpha-tocopherol (vitamin E) and N,N'-diphenyl-*p*-phenylenediamine (DPPD) protected against lipid peroxidation and hepatotoxicity caused by VPA in rats. Conclusive findings from clinical trials specifically investigating the severity or clinical significance of these effects or the appropriate dosage and specific therapeutic benefits of selenium supplementation have yet to be published.

In 1984, Hurd et al.[47] examined several aspects of altered trace-metal status resulting from anticonvulsant therapy using VPA. They found that administering VPA to rats produced a one-third reduction of hepatic selenium and significant reductions of plasma levels of both selenium and zinc. Also, decreased plasma selenium levels characterized patients treated chronically with VPA as their sole anticonvulsant medication. Further, in addressing the disproportionate incidence of hepatotoxicity and other adverse effects among children, these researchers suggested that this "could be due to decreased selenium concentrations when mechanisms for protection against peroxidative damage are not fully developed."

Several research teams have investigated plasma trace element, plasma GSH-Px, and superoxide dismutase (SOD) levels in epileptic children receiving antiepileptic drug therapy. Kurekci et al.[51] found plasma selenium concentrations (as well as those of copper, zinc, manganese, and magnesium) of patients undergoing valproate (or carbamazepine) monotherapy were not statistically different from those of control subjects, but that plasma GSH-Px activities in the VPA group were higher than in the control group, and the difference was statistically significant. Subsequently, Graf et al.[49] compared antioxidant enzyme activities in 15 children with a history of serious adverse experience (SAE) related to VPA therapy to those of 35 patients with good clinical tolerance of VPA, and 50 healthy, age-matched subjects. In patients who had SAEs, GSH-Px was significantly depressed, and glutathione reductase (GSSG-R) was significantly elevated relative to values for the other groups. Selenium and zinc concentrations were lower in SAE patients than in controls. The authors concluded that individual susceptibility played a critical role in SAEs caused by VPA therapy and that selenium-dependent antioxidant activity appeared to be central to that protective function. In 2002, Verrotti et al.[52] published their findings from a clinical trial of sodium valproate and carbamazepine (CBZ) therapy for 1 year on serum selenium, copper, zinc, GSH-Px, and SOD levels in 36 epileptic children. They reported no initial differences in levels of all parameters studied between controls and epileptic subjects and that, after 1 year of medication, patients treated with VPA and CBZ continued to show normal values.

Conclusive judgments as to the interaction between VPA and selenium await further evidence from human clinical trials. Hepatotoxicity and other adverse effects attributable to VPA appear to be related to a number of known and unknown factors, including, in some measure, diminished antioxidant capacity resulting from depleted selenium and glutathione levels, age-related immaturity of necessary detoxification functions, and individual pharmacogenomic variability in tolerance of VPA and its metabolites.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Valproic acid, along with other forms of conventional anticonvulsant therapy, is associated with drug-induced nutrient depletion and deficiency patterns adversely affecting a wide range of micronutrients, including selenium. Use of VPA produces numerous adverse effects, especially on the liver, but no conclusive evidence has emerged to demonstrate the clinical role of selenium, or other micronutrients supporting antioxidant and detoxification processes, in countering these adverse effects or in the treatment of the underlying pathology of epilepsy.

Preliminary evidence indicates a potential risk of selenium deficiency associated with VPA in some individuals and groups, even though there may be no consensus as to its prevalence or clinical significance. Inadequate presence of selenium in dietary sources is common, especially in areas where soils are selenium deficient. Whether or not sufficient evidence exists to support use of concomitant selenium in relation to the direct adverse effects of VPA therapy, a general consensus exists that sustained selenium deficiency, and other nutrient depletion patterns, constitute an enhanced and avoidable risk for susceptibility to cancer and other chronic diseases. In particular, selenium deficiency may contribute to increased oxidative DNA damage, and genomic instability is considered a significant factor in setting the stage for carcinogenesis. Thus, administration of selenium at levels of 200 to 400 µg per day, depending on age, weight, and health status, may be beneficial in terms of reducing specific adverse effects caused by anticonvulsant treatment with VPA, as well as broader increased risk factors. Physicians prescribing VPA are advised to discuss the risks, especially adverse effects and potential depletion patterns, associated with VPA treatment and suggest options for supportive nutritional interventions, particularly antioxidants and selenium, or refer to a physician or other health care professional experienced in nutritional therapies.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Bleomycin

Bleomycin (Blenoxane).

Recent research indicates that selenium might interfere with the antineoplastic action of bleomycin, an antibiotic used in the

treatment of various cancers. Bleomycin is known to damage DNA by free-radical mechanisms. In two rat studies published in 2001, Desai et al.[53,54] found that selenium may inhibit the therapeutic action of bleomycin, most likely by enhancing the catalytic function of glutathione peroxidase.

HMG-CoA Reductase Inhibitors (Statins)

Atorvastatin (Lipitor), fluvastatin (Lescol, Lescol XL), lovastatin (Altocor, Altoprev, Mevacor); combination drug: lovastatin and niacin (Advicor); pravastatin (Pravachol), rosuvastatin (Crestor), simvastatin (Zocor); combination drug: simvastatin and extended-release nicotinic acid (Niaspan).

Recent studies suggest that antioxidant nutrients may interfere with the therapeutic action of 3-hydroxyl-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, popularly known as statins, particularly simvastatin (Zocor), in combination with niacin. The synergistic interaction between simvastatin and niacin has been shown to be effective in reducing low-density lipoprotein (LDL) cholesterol and increasing high-density lipoprotein (HDL) cholesterol levels in individuals with hyperlipidemia, particularly in the context of personal history of cardiac events, malignant family history of heart disease, elevated inflammatory index markers (IIMs), or other high-risk factors.[55] At this point, evidence from clinical trials, particularly two papers published in 2001 by Cheung, Brown, et al.[56,57] at the University of Washington, suggests that coadministration of antioxidants (including selenium) may diminish this combination medication's effectiveness in elevating HDL cholesterol. However, evidence thus far indicates that the interaction observed was between one or more of the antioxidants used and niacin, rather than involving the statin agent directly. Furthermore, no evidence has emerged to indicate that selenium in particular is responsible for this putative undesirable effect.

NUTRIENT-NUTRIENT INTERACTIONS

S-adenosylmethionine (SAMe)

The toxicity of selenium at high dosages, especially in its inorganic forms, is largely attributable to its depletion of SAMe reserves. SAMe is the body's principal methyl donor, and the metabolism of inorganic selenium requires both extra methyl donors and higher levels of antioxidants on its way to becoming methylselenol.

Total Parenteral Nutrition (TPN)

Numerous researchers and clinicians have reported deficiency and depletion patterns involving a wide range of micronutrients, particularly trace elements, in patients receiving TPN, especially over extended periods. Selenium can prevent adverse effects, particularly cardiomyopathy. A 1997 German review concluded: "The dietary parenteral selenium requirement can be calculated on the basis of the maximal gene expression of the selenoprotein plasma glutathione peroxidase (plGPx). In total parenteral nutrition a daily requirement of 0.01 µmol/Kg body weight for adults and 0.025 µmol/Kg body weight for children can be seen as adequate and safe."[58] Similarly, a 1996 Japanese review of the subject concluded: "Requirement of trace elements for human adults from TPN estimated as follows. Zinc: 3-4 mg/day, copper: 0.02-0.05 mg/day, iron: 1-2 mg/day, manganese: 0.15-0.80 mg/day, selenium: 0.02-0.05 mg/day, chromium: 0.01-0.015 mg/day, molybdenum: 0.075-0.250 mg/day and iodine: 0.070-0.140 mg/day."[59]

Vitamin E

Selenium potentiates the antioxidant activity of vitamin E. Selenium and vitamin E act synergistically and are more effective when taken together.

HERB-NUTRIENT INTERACTIONS

Milk Thistle (*Silybum marianum*) and Alpha-Lipoic Acid

Berkson[60] reported that symptomatic hepatitis C patients with elevated transaminases who were placed on a "conservative triple antioxidant" therapy comprising alpha lipoic acid, selenium, and *Silybum marianum* (milk thistle) were spared hepatic transplantation, showed improved laboratory indices, and returned to normal working life. Multi-antioxidant therapy combining alpha lipoic acid with other antioxidant agents, such as selenium and the herb milk thistle, is synergistic in hepatitis C therapy and may provide a cost-effective alternative approach, even in individuals with a poor prognosis.

The 61 citations for this monograph, as well as additional reference literature, are located under Selenium on the CD at the back of the book.

Zinc

Nutrient Name: Zinc.
Elemental Symbol: Zn.
Forms: Zinc acetate, zinc arginate, zinc ascorbate, zinc aspartate, zinc carbonate, zinc citrate, zinc gluconate, zinc glycerate, zinc glycinate, zinc histidinate, zinc lactate, zinc methionate, zinc monomethionine, zinc oxide, zinc picolinate, zinc selenate, zinc sulfate, zinc undecylenate.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Amphetamines Related stimulant medications Methylphenidate ⊕⊕⊕	Zinc may directly benefit patients with ADHD, and coadministration with mixed-amphetamine salts may provide enhanced therapeutic effects. Benefit may be more probable in older and heavier individuals with low zinc and free fatty acid levels, but research indicates children may also benefit. Adverse effects unlikely. Further research warranted.	Coadminister, when indicated. Complement with low-dose copper with long-term use.
Androgens ⊕⊕	Zinc is key to normal male sexual function, including testosterone formation, spermatogenesis, and prostate function, as well as ovulation and fertilization in females. Deficiency can cause hypogonadism, and administration can elevate testosterone levels, raise sperm counts, and enhance action of androgen therapy, especially when pretreatment zinc levels are low. Adverse effects unlikely. Further research warranted.	Consider coadministration for synergistic effect. Complement with low-dose copper with long-term use.
Antibiotics, oral ⊕⊕/⊕✗/✗	Zinc plays central role in immunocompetence and may enhance acute immune response. Combination of oral antibiotics and zinc may benefit some patients, particularly those with compromised zinc status, but may be contraindicated in treatment of pneumonia during hot weather. Further research warranted.	Coadminister, when indicated, in infants and children, especially with poor zinc nutriture. Routine pediatric prophylaxis may be contraindicated.
Antibiotics, topical ⊕⊕	In addition to zinc's general activity in supporting healthy skin and immune function, its bacteriostatic activity against *Propionibacterium acnes* and its role in polymorphonuclear leukocyte chemotaxis are beneficial in treating inflammatory acne. Coadministration of zinc, topical or oral, with topical antibiotics may enhance treatment of acne vulgaris. Adverse effects unlikely. Further research warranted.	Consider coadministration of oral zinc for synergistic effect. Complement with low-dose copper with long-term use.
Antidepressants, tricyclic Antidepressants, selective serotonin reuptake inhibitor (SSRI) ⊕⊕	The central nervous system and hippocampal and cortical neurons, in particular, rely on high concentrations of zinc to modulate the excitatory (glutamatergic) and inhibitory (GABAergic) amino acid neurotransmission pathways. Administration of zinc increases levels of synaptic pool zinc in hippocampus and promotes changes in brain similar to antidepressants. Zinc deficiency may contribute to depression, and coadministration may potentiate activity of antidepressant medications by one or more mechanisms. Further research warranted.	Consider coadministration of oral zinc for synergistic effect. Complement with low-dose copper with long-term use.
Captopril, enalapril Angiotensin-converting enzyme (ACE) inhibitors ≈≈/☼	ACE inhibitors possess a prominent zinc-binding moiety that binds to zinc ions. Zinc depletion at tissue levels and possibly deficiency can occur, with effects of captopril being more rapid than those of enalapril. Concomitant zinc can prevent or reverse depletion. Adverse effects unlikely. Further research warranted.	Watch for clinical signs of zinc depletion; lab tests often unreliable. Coadminister to prevent depletion. Complement with low-dose copper during long-term use.
Chlorhexidine ☼/⊕⊕	Coadministration of zinc can enhance binding affinity, reduce severity of chlorhexidine-induced staining, and enhance plaque-inhibiting effect.	Combining zinc with chlorhexidine indicated for reducing adverse effects and increasing efficacy.
